Nitrogen Management Affects Nitrous Oxide Emissions under Varying Cotton Irrigation Systems in the Desert Southwest, USA

Kevin F. Bronson,* Doug J. Hunsaker, Clinton F. Williams, Kelly R. Thorp, Sharette M. Rockholt, Stephen J. Del Grosso, Rodney T. Venterea, and Edward M. Barnes

Abstract
Irrigation of food and fiber crops worldwide continues to increase. Nitrogen (N) from fertilizers is a major source of the potent greenhouse gas nitrous oxide (N_{2}O) in irrigated cropping systems. Nitrous oxide emissions data are scarce for crops in the arid western United States. The objective of these studies was to assess the effect of N fertilizer management on N_{2}O emissions from furrow-irrigated, overhead sprinkler-irrigated, and subsurface drip-irrigated cotton (*Gossypium hirsutum* L.) in Maricopa, AZ, on Trix and Casa Grande sandy clay loam soils. Soil test- and canopy-reflectance-based N fertilizer management were compared. In the furrow- and overhead sprinkler-irrigated fields, we also tested the enhanced efficiency N fertilizer additive Agrotain Plus as a N_{2}O mitigation tool. Nitrogen fertilizer rates as liquid urea ammonium nitrate ranged from 0 to 233 kg N ha^{-1}. Two applications of N fertilizer were made with furrow irrigation, three applications under overhead sprinkler irrigation, and 24 fertigations with subsurface drip irrigation. Emissions were measured weekly from May through August with 1-L vented chambers. N_{2}O emissions were not agronomically significant, but increased as much as 16-fold following N fertilizer addition compared to zero-N controls. Emission factors ranged from 0.10 to 0.54% of added N fertilizer emitted as N_{2}O-N with furrow irrigation, 0.15 to 1.1% with overhead sprinkler irrigation, and <0.1% with subsurface drip irrigation. The reduction of N_{2}O emissions due to addition of Agrotain Plus to urea ammonium nitrate was inconsistent. This study provides unique data on N_{2}O emissions in arid-land irrigated cotton and illustrates the advantage of subsurface drip irrigation as a low N_{2}O source system.

Core Ideas
- N_{2}O emissions under overhead sprinkler and furrow irrigation were 0.5 to 1 %.
- Subsurface drip irrigation combined with 24 fertigation events had an emission factor of 0–0.1%.
- The use of enhanced efficiency fertilizers NBPT and DCD had inconsistent mitigation effects on N_{2}O emissions.
- Reduction in N_{2}O emissions with canopy reflectance-based N management was inconsistent.

Abbreviations: DCD, dicyandiamide; EEF, enhanced efficiency fertilizer; EF, emission factor; ET, evapotranspiration; FI, furrow irrigation; NBPT, N-(n-butyl) thiophosphoric triamide; NDVI, normalized difference vegetation index; OSI, overhead sprinkler irrigation; SDI, subsurface drip irrigation; UAN, urea ammonium nitrate; WFPS, water-filled pore space.
Nitrous oxide (N\textsubscript{2}O) is a potent greenhouse gas with a heat-trapping potential 265 times that of carbon dioxide (IPCC, 2014). Agricultural practices, particularly N fertilizer application, make up approximately 74% of the N\textsubscript{2}O emissions in the United States (USEPA, 2015). Nitrous oxide is produced in cropped soils during denitrification, the anaerobic reduction of nitrate (NO\textsubscript{3}\textsuperscript{-}) to di-nitrogen (N\textsubscript{2}), and during nitrification, the oxidation of ammonium (NH\textsubscript{4}\textsuperscript{+}) to NO\textsubscript{3}\textsuperscript{-} (Firestone and Davidson, 1989; Thapa et al., 2016). Irrigation generally results in increased N\textsubscript{2}O emissions, by stimulating soil C and N cycling and reducing soil O\textsubscript{2} (Trost et al., 2013; Scheer et al., 2013; Rolston et al., 1982), although not in all cases (Maharjan et al., 2014). Irrigated cotton production in arid regions is typically water-intensive and can also be energy-intensive if the water is conveyed across more than a 30-m elevation gradient. According to Maraseni et al. (2010), greenhouse gas emissions in Australia from irrigated cotton are primarily from electricity used in pumping for irrigation and second from N\textsubscript{2}O emissions from N fertilizer.

During the last 30 yr, hundreds of field studies have measured N\textsubscript{2}O emissions from N-fertilized cropped fields, mostly on corn (\textit{Zea mays} L.) (Halvorson et al., 2014; Hatfield and Venterea, 2014; Thapa et al., 2016). Many of those studies tested enhanced efficiency fertilizers (EEFs) such as Agrotain Plus (Koch Agronomic Services), which consists of the urease inhibitor N-(n-butyl) thiophosphoric triamide (NBPT), and the nitrification inhibitor, dicyandiamide (DCD). The purpose of EEFs like NBPT and DCD are to keep N fertilizer in the NH\textsubscript{4} form as long as possible so that less N\textsubscript{2}O is available for leaching and/or promoting denitrification-derived losses of N\textsubscript{2}O and N\textsubscript{2} (Venterea et al., 2012; Halvorson and Del Grosso., 2013). Mitigation of N\textsubscript{2}O emissions associated with nitrification can also be achieved with EEFs (Bronson et al., 1992; Venterea et al., 2012; Qiao et al., 2015; Thapa et al., 2016). The ultimate goal of EEF use is to improve N use efficiency in crops and improve yields. Fewer N management studies have been conducted on cotton than corn (Scheer et al., 2008; Liu et al., 2010, Wang et al., 2013). In fact, with the exception of studies in Australia (Rochester, 2003; Grace et al., 2010; Rochester et al., 2015; MacDonald et al., 2016; Scheer et al., 2016; Grace et al., 2016), N\textsubscript{2}O emissions studies in cotton are much rarer than for other crops. Placement of N fertilizer is also an important tool to efficient N management (Halvorson and Del Grosso, 2013). We are aware of no measurements of N\textsubscript{2}O emissions following fertigation into FI.

There is a great deal of interest in calculating "emission factors" (EEFs) with N\textsubscript{2}O flux field data from N fertilizer treatments. This is simply the percentage of applied N fertilizer emitted as N\textsubscript{2}O after accounting for the fluxes from zero-N treatments. The IPCC makes the assumption that on average, a single emission factor of 1.0% can be used for N-fertilized field crops (De Klein et al., 2006), but emission factors are often lower or higher than 1.0% (Lesschen et al., 2011). Emission factors are a useful way to compare the impact of different management practices on N\textsubscript{2}O emissions, particularly for varying N fertilizer rates or EEF treatments (Dobie and Smith, 2003; Liu et al., 2010; Lesschen et al., 2011; Scheer et al., 2013; Halvorson et al., 2014; MacDonald et al., 2015).

Recent research in Texas and Arizona has demonstrated that the use of proximal sensing of canopy reflectance can allow for reduced N fertilizer rates without affecting cotton lint yields (Bronson et al., 2011, 2017). Little research has been done on whether canopy reflectance-based N management translates to reduced N\textsubscript{2}O emissions (Yabaji et al., 2009; Venterea et al., 2012).

Nitrous oxide emission studies with SDI are few (Kennedy et al., 2013; Dogan et al., 2008; Yabaji et al., 2009; Kallenbach et al., 2010). Studies comparing N\textsubscript{2}O emissions from different irrigation systems, such as FI and OSI in corn, are likewise rare (Nelson and Terry, 1996). Cayuela et al. (2017) reported in a meta-analysis that EFs from SDI were less than with OSI in Mediterranean cropping systems, but no cotton studies were included. Guardia et al. (2017) reported that surface drip irrigation and an EEF resulted in reduced N\textsubscript{2}O emissions compared with sprinkler irrigation in corn. Sánchez-Martin et al. (2008) found that N\textsubscript{2}O emissions in melon (\textit{Cucumis melo} L.) in Spain were lower with surface drip irrigation than with FI.

No previous studies have been done evaluating the effects of N management for different irrigation systems on N\textsubscript{2}O emissions in irrigated cotton in the US desert Southwest. The objective of this study was to compare N\textsubscript{2}O emissions and emission factors with various N management treatments in a surface-irrigated field, an overhead sprinkler-irrigated field, and a subsurface drip-irrigated field, all furrowed for cotton in Arizona. We hypothesize that N management approaches such as knitting-in of N, use of EEFs, or reflectance-based N management can result in less N\textsubscript{2}O emissions compared with fertigating urea ammonium nitrate (UAN) in FI, or soil test-based N approaches without EEFs.

Materials and Methods

Nitrogen fertilizer management studies were conducted at Maricopa, AZ, for six consecutive years (2012–2017). The Maricopa Agriculture Center research farm is located at 33.067 N, 111.97 W and 360 m above sea level and has average annual rainfall of 200 mm. Furrow irrigation, OSI, and SDI were used for 2012–2013, 2014–2015, and 2016–2017, respectively. Furrow irrigation and OSI fields had 30-cm-high beds constructed every year with 1-m spacing; the SDI field had 15-cm-high beds, also at 1-m spacing. The soil at the FI and OSI fields (500 m apart) is a Trix sandy clay loam/sandy clay (fine-loamy, mixed, superactive, calcareous, hyperthermic Typic Torrifluvent). Casa Grande sandy loamy/sandy clay loam (fine-loamy, mixed, superactive, hyperthermic, Typic Natargid) is the soil at the SDI site, which is 1.3 km from the other two sites. The specific N management treatments for each of the three studies are detailed in Tables 1 to 3. The experimental design for all studies was a randomized complete block, with three replicates for FI and SDI and four replicates in OSI.

In March of each year, pre-plant soil sampling to 1.8-m depth for NO\textsubscript{3}-N was done at two to four locations per plot. Nitrate-N in the 0- to 90-cm soil depth was used to determine the N fertilizer rate for a soil test-based treatment as detailed in Tables 1 to 3. Zero-N control plots were established in all six site-years. Canopy reflectance-based N management treatments were tested, where N rates were initially set at 50% of the soil test treatments. The goal of this treatment was to reduce N fertilizer use without affecting yields. Weekly canopy reflectance measurements with the active optical sensor CropCircle ACS-470 (Holland Scientific Inc.) were used to determine when reflectance plots
showed N deficiency. Specifically, when the normalized difference vegetation index (NDVI) amber was significantly less than the NDVI amber in the soil test treatments, N fertilizer rates were raised to match the soil test N rate (Bronson et al., 2011, 2017). In 2014–2015, under OSI, a second reflectance-based N treatment was added, which used 1.3* soil test N rate as the reference (Table 2). Cotton ‘Delta Pine 1044 B2RF’ was planted in late April to 1 May from 2012 to 2015, and cotton ‘Delta Pine 1549 B2XF’ was planted in mid-April in 2016 and 2017. In 2012 and 2013, FI plots were eight rows 1 m wide by 170 m long. In 2014 and 2015 under OSI, plots were six rows 1 m wide by 37 m long. In 2016 and 2017, plots were eight rows 1 m wide by 100 m long in the SDI field.

The N fertilizer source used in all of the studies was UAN, 320 g N kg⁻¹. In the FI study, N fertilizer treatments (Table 1) were applied in two split applications of N applied at first square

§ Initial N fertigation rate equals 50% treatment 2; rate was increased when normalized difference vegetation index (NDVI) was significantly less than treatment 2 NDVI.
and first bloom either by fertigating in the water run (with a 110 L h\(^{-1}\) diaphragm pump) or spraying-N in the side of the bed. 10 cm from the plant row, the day before FIs. Nitrogen fertilizer treatments (Table 2) in the OSI study were applied in three doses (first square, first bloom, and midbloom) with a high clearance tractor to spray N into the furrow with fertilizer nozzles just before OSI events. More details of the FI and OSI study are reported in Bronson et al. (2017). In the SDI study, N treatments (Table 3) were fertigated in 24 events in a 6-wk period from first square to midbloom. Fertigations were made for each N-fertilized, 8-row by 100-m plot with a 30 L d\(^{-1}\) diaphragm pump.

Fertigations were performed on a Shimadzu 2014 gas chromatograph (Shimadzu Scientific Instruments) fitted with a Ni electron capture detector at 340°C with a 95% argon–5% methane carrier gas (Mosier and Mack, 1980). Nitrous oxide fluxes were calculated according to the logarithmic equation of Hutchinson and Mosier (1981). If the increase in N\(_2\)O concentration in the chamber headspace in the 12- to 24-min period was less than the 0- to 12-min increase in concentration, then linear regression was used, as suggested by Ventera and Baker (2008).

On each morning that N\(_2\)O flux sampling occurred, percentage volumetric soil water content for the 0- to 15-cm soil depth was determined with a portable time domain reflectrometer (MiniFrase, Soil Moisture, Inc.). Water-filled pore space (WFPS) was calculated as described by Linn and Doran (1984). Soil temperature at 15 cm was also measured with a digital thermometer.

Nitrous oxide emissions data were analyzed by date, and with date as a repeated measures effect on cumulative, seasonal N\(_2\)O emissions, with a mixed model using SAS (SAS Institute, 2013). Replicate was considered random, and N treatment, date, and date \(\times\) N treatment were considered fixed. Since N\(_2\)O data often has a log-normal distribution, the statistical analysis was also conducted using PROC GLIMMIX with a log distribution. The significance levels of the F statistics for treatments in the mixed models analysis were not remarkably different between the normal and log-normal-transformed data. We therefore only present nontransformed data in all cases.

PROC CORR was used to correlate N\(_2\)O flux with soil moisture and soil temperature for each date (SAS Institute, 2013). Emission factors were calculated for each site-year by subtracting the zero-N seasonal mean N\(_2\)O emission, from the seasonal mean N\(_2\)O emission for each N treatment and dividing by the N fertilizer rate, as suggested by Ventera et al. (2013).

**Results**

Nitrous oxide fluxes were apparent in FI early in the season after N fertilizer applications (Fig. 1), with the exception of the second N dose in 2013, when relatively low (<0.2 g N ha\(^{-1}\) h\(^{-1}\)) fluxes were observed (Fig. 1b). Under OSI in 2014 (Fig. 2a), where three applications of N were made, elevated N\(_2\)O fluxes above 0.5 g N ha\(^{-1}\) h\(^{-1}\) were observed following the first N dose, none after the second dose, and a small flux was detected after the third N dose during 2014 (Fig. 2). In contrast, with OSI in 2015, the largest N\(_2\)O fluxes (1.4–5.5 g N\(_2\)O-N ha\(^{-1}\) h\(^{-1}\)) appeared between the second and third N application. With both FI and OSI, on most dates with observable N\(_2\)O emissions, the fluxes were significantly greater with N fertilizer than the zero-N treatments. The large N\(_2\)O fluxes observed with FI and OSI were in association with WFPS of >80% (Fig. 1 and 2). On the other hand, N\(_2\)O fluxes in SDI did not exceed 0.4 g N ha\(^{-1}\) h\(^{-1}\) (Fig. 3). In 2016, no effect of N fertilizer on N\(_2\)O fluxes were observed in SDI on any dates. In 2017, N fertilizer treatments had significantly higher N\(_2\)O fluxes than zero-N plots at both irrigation levels, but the fluxes were very small (<0.2 g N\(_2\)O-N ha\(^{-1}\) h\(^{-1}\)) (data not shown).

Figures 1 to 3 also show soil moisture percentage measured by time domain reflectrometer for the 0- to 15-cm depth as WFPS. The WFPS ranged from 40 to 100% with FI and from 50 to 90% with OSI (Fig. 1 and 2). The 15-cm depth of the time domain reflectometer probe was not deep enough to reach the wet zone of soil near the emitters in SDI. In SDI, WFPS ranged from just 33 to 50% in 2016 and 23 to 39% in 2017. The late season spike to 67% WFPS in 2017 was due to a 30-cm rain (Fig. 3). Weak but significant positive correlations between weekly N\(_2\)O fluxes and soil moisture as well as soil temperature at 15 cm were infrequent (data not shown).
Tables 1 to 3 show the seasonal, cumulative \( \text{N}_2\text{O} \) emissions by treatment for the three irrigation system-studies. Nitrous oxide emissions were affected by N fertilizer in all four site-years of FI and OSI from 2012 to 2015 (Tables 1–2). The FI studies exhibited maximum emissions in 2013 of 994 g \( \text{N}_2\text{O}-\text{N} \) ha\(^{-1}\) with 119 kg 32–0–0 N ha\(^{-1}\) with Agrotain Plus (Table 1). Large seasonal \( \text{N}_2\text{O} \) fluxes were observed in the OSI studies of 2015 with a maximum emission of 1620 g \( \text{N}_2\text{O}-\text{N} \) ha\(^{-1}\) at a 131 kg fertilizer-N ha\(^{-1}\) rate in 2015 (Table 2). The buried drip study in 2016 had seasonal \( \text{N}_2\text{O} \) emission that did not exceed 300 g \( \text{N}_2\text{O}-\text{N} \) ha\(^{-1}\) (Table 3). In addition to low \( \text{N}_2\text{O} \) emissions in the SDI study, there was no increase with N fertilizer relative to zero-N, but there was in 2017.

Among N-fertilized treatments, differences in \( \text{N}_2\text{O} \) emissions for the six site-years of data were infrequent and inconsistent. With FI, knifing-in of N resulted in lower \( \text{N}_2\text{O} \) emissions than fertilizing, but only in 2012 (Table 1). Ammonium sulfate and UAN with Agrotain Plus had similar \( \text{N}_2\text{O} \) emissions to UAN alone. Under OSI, the addition of Agrotain Plus to UAN reduced \( \text{N}_2\text{O} \) emissions compared with UAN only in 2014 with the soil test N rate of 179 kg N ha\(^{-1}\) (Table 2). There was no effect of Agrotain Plus on the two reflectance-based N treatments in 2014 or on the three treatments in 2015 with Agrotain Plus. The well-fertilized reference treatment of 1.3*soil test for the second reflectance strategy with OSI had greater \( \text{N}_2\text{O} \) emissions than the soil test treatment in 2015, but not in 2014. Reflectance-based N management in the OSI used reduced rates of N fertilizer compared with the soil test treatments (Table 2). However, this resulted in reduced \( \text{N}_2\text{O} \) emissions in 2015, but not in 2014. There was no effect of N management or irrigation level on \( \text{N}_2\text{O} \) emissions with SDI in 2016 (Table 3). In 2017, there was no effect of reflectance management with a reduced N rate or irrigation level.

**Discussion**

The inconsistent effects of Agrotain Plus on \( \text{N}_2\text{O} \) emissions observed here were in contrast to some results with Agrotain Plus in corn, which have shown significant mitigation of \( \text{N}_2\text{O} \) emissions (Halvorson et al., 2014; Thapa et al., 2016). However, Watts et al. (2015) also reported no effect on \( \text{N}_2\text{O} \) emissions from DCD and NBPT addition to solid urea applied in rainfed cotton in Alabama in a 3-yr study. The DCD in Agrotain Plus probably breaks down quickly in high temperature environments, making its use as an \( \text{N}_2\text{O} \) emission inhibitor inconsistent (Bronson et al., 1989). The large \( \text{N}_2\text{O} \) fluxes in FI and OSI (Fig. 1 and 2) were likely from denitrification, rather than nitrification, as WFPS was >80% at these times (Linn and Doran, 1984; Bateman and Baggs, 2005). It is not possible to infer the source of \( \text{N}_2\text{O} \) emissions with SDI from the WFPS data, since as mentioned earlier, they were underestimated with the deep emitter line.

The in-season N management strategy of using canopy reflectance greatly reduced N rates in all six site-years. This approach has potential for reducing \( \text{N}_2\text{O} \) emissions, but in these studies, reduced \( \text{N}_2\text{O} \) emissions were only observed in 2015 under the OSI. Lint yields in those treatments had small (100–150 kg lint ha\(^{-1}\)) but statistically significant reductions compared with the soil test-based N treatments lint yields (Bronson et al., 2017). In the 2 yr of FI and in 2014 under OSI, reflectance-based N treatments did not affect lint yields compared with the soil test treatments (Bronson et al., 2017). We did not measure \( \text{N}_2\text{O} \) emissions in the reflectance-based N plots in the FI study.
Correlations between N\textsubscript{2}O emission and soil water or temperature were inconsistent. Watts et al. (2015) reported positive correlations between N\textsubscript{2}O emissions in rainfed cotton and soil temperature and soil moisture in 2 of 3 yr. The absence of N\textsubscript{2}O emissions in the second half of the season in FI and OSI from 2012 to 2015 was likely due to the fact that N fertilization events were finished and that large plant biomass nitrogen uptake removed most of the available soil NO\textsubscript{3}, and not due to a lack of soil moisture.

That N\textsubscript{2}O emissions from cropping systems are rarely of economic importance at the farm level does not necessarily detract from its importance as a greenhouse gas. That N\textsubscript{2}O emissions from cropping systems are rarely of economic importance at the farm level does not necessarily detract from its importance as a greenhouse gas. There was a two- to fivefold increase in seasonal N\textsubscript{2}O flux in the FI study of 2012–2013 (Table 1). In the OSI, a 16-fold increase in seasonal N\textsubscript{2}O flux was observed, with the 1.3\times soil test rate of 233 kg N ha\textsuperscript{-1} in 2014 (Table 2). The soil test treatment with OSI had a 16- and 5-fold increase in N\textsubscript{2}O emissions for 2014 and 2015, respectively. The reduced reflectance-based N rates with OSI were in the range of a threefold increase above zero-N treatment. The SDI in 2017 saw a multifold increase in N\textsubscript{2}O emissions of the soil test treatment to 218 g N ha\textsuperscript{-1} at low water compared with zero-N plot emission at 70% ET of 6 g N ha\textsuperscript{-1} (Table 3). However, the low N\textsubscript{2}O fluxes with soil test-based N rates at both irrigation levels was in the range of the zero-N emissions in FI and OSI.

Note that there were no statistical tests to compare N\textsubscript{2}O emissions among the three irrigation studies. This is because there were differences in the treatments, N rates, soil type, and the number of replicates, that is, there were three separate 2-yr, replicated studies. The zero-N treatments were consistent for 6 yr, except for the irrigations. The emission factor calculations can be used to standardize the variations in N fertilizer rate.

In FI cotton in Australia, EFs varied from 0.29, 0.58, and 1.83% for 100, 250 (current average producer rate), and 300 kg N ha\textsuperscript{-1} fertilizer rates, respectively (MacDonald et al., 2015; Grace et al., 2016). In our FI study, EFs of 0.5% were observed with N rates of 119 and 148 kg N ha\textsuperscript{-1} (Table 1), whereas the Australian FI studies did not measure EF of 0.5% until the N fertilizer rate was increased to 250 kg N ha\textsuperscript{-1} (Grace et al., 2016).

In our data from 2012 to 2017, the N\textsubscript{2}O EFs measured were in line with the IPCC factor in just 4 of the 14 N-fertilizer treatment-year combinations under OSI (Tables 1–3). As a comparison, a N\textsubscript{2}O emission factor of 0.5% of an 134 kg N ha\textsuperscript{-1} one-dose ground application of UAN in a center pivot-irrigated cotton field in West Texas was reported by Halvorson et al. (2012). Two recent studies on N\textsubscript{2}O emissions with sprinkler-irrigated cotton in China reported EF of 1.0% (Liu et al., 2010; Wang et al., 2013), and a study in Uzbekistan measured an EF of 1.5% under FI (Scheer et al., 2008). In Queensland, Australia, in a clay soil, EFs ranged from 0.1 to 0.5% for N rates from 90 to 270 kg N ha\textsuperscript{-1} under an OSI (Scheer et al., 2016). The EF in our OSI study ranged from 0.4 to 1.1% (Table 2), the high value of which greatly exceeded the EF in the Australian OSI study. The large N\textsubscript{2}O emissions and EF with OSI were not expected. Apparently, the two to four times a week irrigation frequency of the OSI created optimal moisture conditions for N\textsubscript{2}O emission via nitrification and denitrification. Leaching of losses of NO\textsubscript{3} were reported in the FI study, but not the OSI (Bronson et al., 2017). In this companion paper to the present study, Bronson et al. (2017) reported that deep percolation was as high as 11%
of irrigation and rain in the FI study but was negligible in the OSI. Nelson and Terry (1996) reported greater denitrification losses, measured by acetylene blockage, on a clay loam soil with FI than with OSI in Utah. They attributed this result to the disruption of soil aggregates and crusting under FI. This in turn led to reduced infiltration of irrigation water and a higher percentage of water-filled pore space. We did not observe crusting or reduced infiltration in our FI study.

Surface (0–15 cm) soil moisture dipped to as low as 40% WFPS between irrigations with FI (Fig. 1). Soil drying and cracking was observed in the surface layer of the FI fields during the last 4 to 5 d of 10-d irrigation cycles. No surface soil cracking occurred in the OSI field. Cotton plants were therefore probably taking up water in the subsoil when surface soil cracking occurred, whereas root water uptake probably occurred in the consistently wet soil surface in OSI. Most N₂O production in soil occurs in the surface soil layers, with very little in the subsoil, since soluble carbon (C) is limited (Parkin and Meisinger, 1989). The combination of frequent, light irrigations in OSI apparently resulted in high moisture and high soluble C conditions that promoted nitrification and denitrification losses of N₂O.

The most notable finding in our study was with SDI, where the EF was 0% in 2016 and 0.1% in 2017 (Table 3). Yabaji et al. (2009) measured a zero EF of surface emissions of N₂O + N₂ in SDI cotton in West Texas with 20+ fertigation events. Subsurface drip irrigation is a highly efficient irrigation system, with little leaching or evaporative losses of irrigation water. Matrix forces wick the water away from the emitter so that saturation is not achieved. Additionally, fertigating in 24 doses in SDI amounts to “spoon feeding” N to the crop. Kallenbach et al. (2010) compared N₂O emission with SDI and FI with a cover crop–tomato (Solanum lycopersicum L.) system in California. In that study, N₂O emissions were similar between SDI and FI, and much greater than reported for these systems here. Nitrogen fertilizer was fertigated in SDI and side-dressed in two splits in FI. However, there were no zero-N treatments in the Kallenbach study, so an EF factor was not calculated.

Conclusions

Nitrous oxide emission factors reached a maximum of 1.1 and 0.5% for OSI and FI, respectively. Emissions of N₂O were very low in the SDI study, with an emission factor of 0 to 0.1%.

The very high number (24) of small fertigations in the SDI study probably contributed to the low emissions. Fertigation of N fertilizer in SDI cotton, therefore, is a very “climate-friendly” management practice. Nitrogen management options such as N placement, use of Agrotain Plus, or reflectance-based N had inconsistent effects on N₂O emissions. With growing worldwide interest in the installation of SDI in arid land cropping systems (Gleick, 2003; Ibragimov et al., 2007; Du et al., 2008; Dogan et al., 2008), these new findings demonstrate that the low N₂O emission factor of SDI can help off-set greenhouse gas emissions associated with SDI.
