Introduction

This report will discuss the effects on soils of continuing operations of the US Sheep Experiment Station (USSES) administered by the Agricultural Research Station (ARS) near Dubois, Idaho. The purpose of the Environmental Impact Statement (EIS), and specifically this report, is to ascertain whether continued operations would lead to degradation of soils resources beyond current conditions, and if the current conditions are in violation of relevant and applicable laws and regulations and Departmental policy and plans. Fieldwork was performed during June and July 2008, and August 2009 to evaluate the existing conditions on the ground.

The project area is the collective properties of the ARS, USSES, totaling 47,340 acres. This includes old ranch lands recognized as Humphrey, Henninger, purchased in the early 1940s, and Headquarters (30,125 acres) and the summer grazing area in the Centennial Mountains (17,215 acres), which is approximately 25 miles due west of Yellowstone National Park.

Currently, the USSES grazes, on average, 3,300 mature sheep on their land base. Part of their mission is to monitor reproductive efficiency with the ultimate goal of increasing production in the context of environmental factors. Sheep numbers are kept below the carrying capacity of the USSES properties. Sheep are held at the headquarters facilities for most of the year, staged in the various pastures with supplemental feeding, and then grazed on the summer range for one to two months depending on weather conditions.

Methodology

Each of the ARS parcels was transected during two separate field visits in 2008 (July 8 through July 12, and August 28 through September 2). Periodic observations of ground cover, surface condition, geology, and, where applicable, stream channel stability and trend were noted. Surface condition used soil indicators from the R4 soil quality monitoring protocol (USDA 2003). A supplemental overview assessment was performed in August 2009.

A classification of soil condition and cover with ratings 1 through 4 was devised to catalogue observations. These classifications were quantified to portray general conditions and spatial trends.

- Condition Class 1 represents soils that have had severe disturbance and are hydrologically impaired. Soil conditions follow USDA Forest Service (2003) criterion for long-term impairments to soil productivity with sparse ground cover, evidence of severe compaction (surface ponding), displacement, or erosion (rills, soil pedestals).
- Condition Class 2 represents soils showing evidence of disturbance with marginal hydrologic functionality, and little or no sign of recent sheet erosion. Soil ground cover and understory vegetation are adequate to resist erosion.
- Condition Class 3 indicates soil conditions reflecting a one-time impairment, but fully recovered hydrologic function.
- Condition Class 4 soils have a minimal sign of impairment, with full recovery of soil and hydrologic function.

Range surveys performed in 2009 by TEAMS range staff were also correlated with results from Keith Klements (1997) to gage soil conditions and long-term trend for soil productivity. Supplemental information was gathered through discussion with USSES staff in addition to Natural Resource

Conservation Service (NRCS) soil scientist Bill Hiatt (Idaho Falls, ID), and Justin Urroti and Ken Scalzone (Dillon, MT), and Bureau of Land Management (BLM) botanist, Wendy Velman (Billings, MT), along with historical assessments obtained from the USSES staff. Soils information is still being developed for the USSES though preliminary mapping concepts from the Clark county survey, and 1990s data collection (1991) was used. This information helped verify the appropriate range sites chosen from which to evaluate range condition. Ultimately, the professional knowledge of the USSES staff, NRCS staff, and BLM were invaluable for evaluating current conditions and trends.

Affected Environment

The ARS properties comprise low and highland areas along the northeastern edge of the Snake River Plain. The highlands serve as summer range and are located within the Centennial Mountains to the northeast of the USSES. The lowlands are lava-dominated sage plains where the sheep are grazed fall through spring.

The Centennials belong to the Rocky Mountain province and consist of folded and thrust sedimentary rocks overlain with basalt and tertiary sediments. Vegetation ranges from mixed conifer to alpine meadow communities. The USSES has two summer ranges:

- West Summer - Includes “Odell”, which is west of O’dell Creek, and, to the east,
- East Summer– Toms Creek

The lowlands are gently sloping lava flow bench lands made up of Quaternary aged lava flows over rhyolite tuffs. These lava flows have interfingered alluvial deposits from the Centennial Mountains, in addition to fine-grained sediments from aeolian (wind-blown loess) and lake (lacustrine) deposits (Stevenson, 1993 unpublished report, Link 2008). The USSES original Headquarters and the acquired old ranch Henninger are located on these lowlands with sage steppe as the dominant plant community. Another old ranch, Humphrey, borders these lowlands on the western foot slope of the Centennial Mountains, near Monida pass and is predominantly sagebrush.

This volcanic or lava plain, increases in elevation to the northeast and generates a strong moisture gradient from Headquarters to Henninger. Annual precipitation is in the range of 8-12 inches near the southwest corner of Headquarters and increases to 17-22 inches in the upper portion of Henninger, due to the orographic lift of the Centennial Mountains (Hiatt, 2009, personal communication). The Centennials proper receive, on average, over 40 inches of precipitation annually primarily as snow (NRCS 1991; Prism Model, USDA Forest Service 2009).

Predominately, moisture and temperature gradients drive vegetation and soil development, although parent material along with other soil forming factors are also very important as well in soil genesis, development and morphology. On the lowlands, the cold temperatures and arid conditions make for slow soil development, in part due to the relatively recent lava flow-rock. The inherent parent material properties of the lava and interbedded alluvium are factors in the formation of both coarse-loamy and fine-loamy and loamy-skeletal soil textures. In this area, soil forming factors lead to predominantly well-drained conditions, which may be limiting plant available water during the growing season. In addition, cold climatic conditions also limit vegetative types to those more adaptive species, especially in areas over 6,200 feet elevation. This is an elevation above which soils are classified cryic; whereby mean annual temperatures are lower than 47 degrees F, thereby nominally shortening the length of the growing season and subsequent use and management of these soils. Headquarters and Henninger Ranch soils trend to cryic conditions. However, the summer pastures with gentle slopes and northern aspects in the

Centennials and foothill Humphrey sites have these more extreme cold air influences (Hiett 2009, personal communication).

For the Headquarters and Henninger Ranches, the degree of soil development on the lava flows is a strong indicator of potential productivity. Lava ridges have very poor productivity potential compared to adjacent concave shaped swales that have accumulated sediment over time in response to water erosion/runoff from exposed bedrock. The basalt exposures, also known as pressure ridges, have lithic soils less than 20 inches deep to hard bedrock, with exposed bare mafic lava rock on the surface. Forage production varies from 250 to 800 pounds per acre on the pressure ridges (NRCS 1991). In contrast, soil development and productivity are accentuated by the microtopography of the lava flows where swales continue to trap alluvial and aeolian (wind-blown loess) sediment. Old alluvium and aeolian deposition from nearby mountain glaciers and Pleistocene-aged Lake Terreton, once located at the foot of the Centennials, provides fine sediment for much of the soil profile (Stevenson 1993, Hiett 2009 personal communication). Production ranges from 1200 to 1600 pounds of forage per acre within these swales based on range site information (SCS 1981, NRCS 1991).

The productivity contrasts on the lava plain are highlighted by the vegetation. The lava pressure ridges support sparse sub-shrub communities compared to adjacent communities where grasses are dominant on deeper, more productive soils. More generally, vegetation includes: three-tip sage (*Artemisia tripartita*) as the dominant vegetation; with needle and thread (*Hesperostipa comata*), bluebunch wheatgrass (*Pseudoroegneria spicata*), prairie junegrass (*Koeleria macrantha*), and sandberg poa (*Poa secunda*) typical grasses. Cheatgrass (*Bromus tectorum*) tends to occupy these less fertile areas in occasional small, less than half-acre clumps.

Soils deepen dramatically to greater than 60 inches in landforms characterized by concave shaped swale bottoms where thicker topsoil (the upper most layer(s) of the soil profile where concentration of organic matter and microorganisms are highest, providing abundant nutrients for plant growth) and subsurface clay accumulation provide increased water holding capacity and cation exchange capacity. Both positive and productive attributes support native and introduced pasture grasses. The swale indicator species are basin big sagebrush (*Artemisia tridentata ssp. tridentata*) and basin wildrye (*Leymus cinereus*).

Soils on the lava plain can also vary according to the type of lava flow; the rough surface aa lava breaks to coarse rock that allows for deeper development and efficiently catches aeolian sediments while the smooth pahoehoe lava formed a viscous and smooth surface that is prone to wind scour. Soils on both Henninger and Headquarters parcels are found on pahoehoe and aa lava.

Across the lava plain, the shift in moisture to the northeast increases the potential vegetative productivity, with subsequent increase of fescue grasses (*Festuca spp.*) closer to the Centennial Mountains. Rainfall increases to 16-22 inches, creating an even-tempered growing environment with most of the carbonates in soil leached to a lower depth below the effective rooting area. The loss of carbonates is marked by increases in mountain big sagebrush (*Artemisia tridentata ssp. vaseyana*) and Idaho fescue (*Festuca idahoensis*) (Ecosite B13-05, B13-39, NRCS (In development)). This increase in moisture is most evident in the Henninger pasture where the lava pressure ridges support aspen (*Populus tremuloides*) instead of sage. The plantings of crested wheatgrass in the southwest corner of Headquarters correlate to the low productive conditions from high carbonates and very low precipitation. These areas represent an altered plant community from the historic vegetation (Ecosite B11b-R011BY010ID, NRCS (In development)).

Henninger ranch soils have greater depth than Headquarters soils because of alluvial deposits and underlying glacial outwash derived from the Centennial Mountains. This alluvium creates planar (flat horizontal, yet two-dimensional depositional) surfaces, with dry meadow conditions that support hay production. Silver sage (*Artemisia ludoviciana*) and mules-ears (*Wyenthia amplexicaulis*) are the

prominent indicators of these semi-wet meadows along with associated vegetation species: death camas (*Zigadenus venenosus*), sedge (*Carex spp.*), and pasture grasses (Kentucky bluegrass (*Poa pratensis*) and timothy (*Phleum pratense*)). These soils have profound thick mollic epipedons (very dark brown to black surface horizon, high in organic matter; characteristically formed under grass) and clay subsoil's, with good productive capacity (R013XY039ID, NRCS (in development)). Adjacent footslopes have moderately steep slopes and inceptic soils on weathered pitchstone obsidian residuum with low nutrient status on colluvial footslopes (R013XY005ID, NRCS (in development)). Range production is upwards of 1,800 pounds forage per acre for hillocks and benchlands, compared to 1,400 pounds forage per acre on alluvial flats for average years.

Soils at Humphrey vary highly due to the minor slump (mass wasting) terrain. Ridge soils are lithic (shallow, less than 20 inches over hard bedrock) and skeletal (more than 35 percent rock (coarse) fragments $\geq 2\text{mm}$ by volume below 10 inches) with poor site quality. Back slope concavities are prone to form from the unconsolidated nature of the parent material; old alluvium gravels and cobbles from the Beaverhead formation. These "slips" form catchments that have deep soils below. Across a hill slope, soil depth varies from moderately deep too deep with dark topsoil's; 20" to 40" and ≤ 40 " respectively. Productivity varies accordingly with the soils below catchment areas supporting robust grassland species. Mountain sage is the dominant component along with Idaho fescue and mountain brome.

The soils on the summer range have strong relationships with aspect and slope location or position on the landscape, which heavily influence productivity and vegetation. Moderately-deep loamy soils (20 to 40 inches deep) occur on ridgetops and hillslopes that support rich forb and short grass communities with forage production in the realm of 1,000-1,200 pounds per acre on windswept ridges, and 2,000-2,400 pounds per acre on deeper soils on protected gentle to rolling slopes. Topsoil contains a higher percentage of organic matter since forming from forb and grassland vegetation. Conifer thickets on side slopes and within protected aspects, shift forest floors to forest herb and conifer litter, with production of forages less than 200 pounds per acre.

Shifts in geology from igneous and metamorphic rocks to sedimentary limestone or shales can lead to shallow and less productive soils than soils deeper than 20 inches. Within soils forming in limestone and shale parent materials, steep armored gravel slopes support a sparse shrub layer and clumped conifers. Toms Creek is a good example of where a contact exists between sedimentary and volcanic rocks in the upper watershed. The western portion of the watershed has steep graveled slopes with sparse snowberry (*Symphoricarpos spp.*) and conifer clumps on shale's and limestone, compared to the forb- and grass-rich eastern portion of the watershed on mafic volcanic material.

Biological soil crusts, mostly unique to semi-arid and arid ecosystems are increasingly being recognized as potentially very important in evaluating range conditions and suitability for grazing. These complex communities are sometimes referred to as cryptogamic, microbiotic, cryptobiotic (soil cyanobacteria, algae, bryophytes, lichens, mosses, and fungi), and micophytic crusts. 'Biological crusts' though is an all-encompassing term that appropriately distinguishes itself from physical crusts, developed genetically/structurally within the soil or from anthropogenic impacts (i.e. cultural land treatments).

Biological crusts are recognized as having important attributes that increase surface soil stability, thus decreasing vulnerability to wind and water erosion, increased water infiltration, and improved soil fertility. Yet these thin (normally $< 4\text{ mm}$ or $5/32\text{ in}$) crusts are fragile and susceptible to damage and even destruction from soil-surface disturbances, such as overgrazing, off-road/off-highway/all-terrain vehicle use, and high-intensity fires. Full recovery, depending on the level or intensity of disturbance, may take less than 10 years, but could take 50 years or more (particularly so for mosses and lichens).

The extent and spatial distribution of crusts though is highly influenced by soil pH, the higher the pH the greater development (particularly when > than 9). In addition, crusts prefer to develop in exposed areas receiving abundant sunlight, spaced among low to a moderate density or basal area cover of bunchgrasses (e.g. Idaho Fescue, Bluebunch wheatgrass, Needlegrass), and not heavily influenced by rhizomatous vascular plants (e.g. Arrowleaf balsamroot, False lupine, Western yarrow). Some crust types may be basically absent or poorly developed in shady conditions, with plant litter on the soil surface, and where sandy soil textures, bedrock or a gravel erosional pavement exists. Crust formation is not as favorable on soils having clayey textures (i.e. exposed subsoils). Some crust species are known to be resistant to trampling (i.e. cyanobacterium), regardless of grazing pressure.

Mosses and lichens would likely be found in protected locations (e.g. under sagebrush, rocky slopes) where grazing pressure was absent or minimal. In addition, soils of the lava plain, where biological soil crusts would be more likely, are forming under a moisture regime bordering between xeric (Mediterranean like climate; cool moist winters, warm dry summers) and aridic (arid-like climate), therefore soil moisture is not as deficient with depth, generally between June and November verses the period between March and November respectively. Therefore, vegetation is somewhat more responsive, developed, vigorous and sustainable than on soils forming in a dryer aridic moisture regime, thus crusts are less likely to thrive and develop.

Little is currently known about occurrence of specific crust species on lands managed for grazing by the USSES. They haven't been described and classified to the species level, nor mapped to date. However, the presence of cyrotogamic crusts were recognized, documented, and evaluated during field inventory work to determine Ecological Rating (range condition) for the vegetation community by NRCS range conservationists on the Headquarters property in 1994. In addition, reconnaissance level observations on other sites in close proximity to the Steep Station ranges (Wendy Velman, 2011, personal communication), would suggest their extent and spatial distribution is limited as these lands are, with exception, well vegetated, often with significant vertical cover.

In absence of comprehensive information on soil biological crusts specific to lands managed for grazing on Sheep Station, assessments, inventory, analysis, and monitoring of this unique microbial community would have to be deferred for possible future research.

Summer Ranges

The vegetation and soil associations of the summer range are unique given the persistent tall forb communities and a high proportion of forbs within grasslands (ARS 2008a). Annual and perennial forbs are typically associated with degraded conditions where forb increases are accompanied by a lack of groundcover (Pyke et al. 2002). However, ongoing studies on the USSES suggest that the high presence of forbs here may be unique to these highlands. Past evaluations vary on the interpretation of conditions with initial estimates showing degraded conditions from the 1950s until the late 1970s, despite a steady grazing rate of 1,000 to 3,000 sheep (ARS 2008a). More recently, interpretations of range conditions shifted from good to excellent ratings and research focused on the prevalence and persistence of these vegetative conditions even within grazing exclosures (2008a).

The persistence of the tall forb communities and high expression of forbs may also be an artifact of pre-settlement grazing disturbance from the late 1800s and early 1900s, and/or from turn of the century wildfire. The Great Burn proposed wilderness along the Montana and Idaho border has similar forb-dominated communities. In particular, there are very tall, mainly monocultural stands of coneflower (*Rudbeckia spp.*) with large expanses of bare soil. This community could be a relic from the 1910 wildfire. Sampled communities in the USSES summer pastures include an abundance of sticky purple

geranium (*Geranium viscosissimum*), sunflower (*Heliomeris multiflora*), lambstongue groundsel (*Senecio integerrimus*), and cinquefoil (*Potentilla gracilis*).

The current vegetation could be considered an altered potential. The rich forb-land communities appear stable (see VanHorn-Ecret 1986, Klements 1997) and are not following traditional concepts for grassland regrowth with perhaps a strong interconnection to the soil biota community. Plants can affect soils nutrient status by forming a positive synergistic relationship (Hobbie 1992, Burke et al. 1998) as demonstrated in California Mediterranean grasslands and Colorado steppe (Vinton and Burke 1995). Moreover, the pertinent implication is the risk for ongoing erosion and sedimentation into creeks.

Current assessments found bare soil mainly along steep ridges and where thin soils occur, particularly in protected concavities. Bare soil is partially a function of the very active slips from the complex topography and protected snow patches. Extensive faulting and bedrock orientation have created unstable conditions that inhibit deep soil development. This is particularly evident in the upper Tom's Creek watershed where shaly slopes have shallow soils. Some limited bare soils are also evident on historical grazing sites, typically bedding areas. These erosion features do not connect to drainage bottoms.

Roads, including a four-wheeled drive jeep trail and the closed mine access road, account for most of the soil Condition Class 1 and 2 in Big Mountain, Odell, and East Summer pastures — about 30 percent of total measured sites, but only a minor fraction of the total summer pasture areas. Some water crossings have low ground cover (less than 50 percent) and minor rilling. Bedding areas have cover between 60 and 95 percent and a minor degree of compaction, though sites are often thin soil over bedrock as they are on ridge tops.

Tilling effects from rodents are pervasive, nearly 100 percent of slump slopes, particularly those with noted convex top surface and well drained. These sites are predominately broad leaf, forbs, and total live ground cover is about 60 percent, plus or minus a few percent.

The imprint of disturbance appears to vary in the summer pastures. Forbs and grasses respond quickly post disturbance as long as excessive soil erosion does not occur. In extreme areas where topsoil's are lost from historic grazing and fire disturbance, recolonization is slow and depends on the slope shape. Upper concave slopes are prone to soil erosion and limit soil redevelopment, while the lower catchments provide deposition zones. These conditions seem tied to geologic contacts with shale and alluvial deposits such as the Beaverhead formation.

The north side ridge opposite of Toms Creek is a good example of slope shape condition on erosion. A quarter acre area on the ridges shows chronic signs of sheet wash. Past grazing and continued use by ungulates aggravate the erosion upslope. Old erosion gullies, likely from historical fire, still are apparent below although vegetated. The downslope position shows active accretion/deposition of soil materials with vegetation responding.

Similar recovery trends are found in a 90-year tracking of range conditions in the subalpine ecosystem of the Wallowa Mountains in northeastern Oregon (Johnson 2003). Accelerated soil erosion rates diminished after the grazing pressure was reduced from historic highs in the 1950s. Recolonization in high meadows was strong as long as soils were somewhat intact. The exception was shallow soils in an erosive slope position. These areas hold a steady state where vegetation remained sparse and sheet erosion common.

Again, Toms Creek provided good context for soil potential. The area likely burned towards the early portion of the 1900s based on feedback from USSSES staff. The current conditions show no erosion beyond dry ravel of the gravels and cobble. Slopes are well armored. These slopes support subshrub and

sparse grass with occasional clumps of conifer. This slope shows possibly an altered potential from the fire and historical grazing use with lower water storage available than adjacent slopes with deeper soils

Headquarters Area

The flatland of Henninger, Humphrey and Headquarters are dominated by three-tip sagebrush. Headquarters is a primary wintering facility and has a more intensive use history than the other areas. In addition, these are historic ranch facilities, and thus have a long term grazing history. Grassland surrogates include rough fescue and Idaho fescue, more abundant in the upper basin allotments of Henninger and Humphrey. Invasive weeds are present, though targeted for control by select grazing and localized herbicide use.

Prescribed burning on the USSES has occurred on Headquarters since 1936, the purpose of which is to restore and improve the range. During the past 30 years, roughly 5,400 acres have burned by prescription, and 13,867 acres from wildfire (see range report). Prescribed burn occurs on approximately 200-acre units and averages 670 acres per year. Since 1990, prescribed burning efforts have used experimental designs to identify differences in impacts between fall and spring burning. The USSES is planning a 30-year fire-return interval, within the 25-40 year natural interval based on the ecological site references for historic range condition (NRCS (in review)).

The Henninger ranch was acquired from private owners in the 1940s. Flood irrigation does occur from midsummer to early fall each year. Farming does not occur, although, once in the past 30 years, a pasture has been cultivated and re-seeded (ARS 2008b).

Headquarters

The results of the summer 2008 survey found about 10 percent of 127 data points are soil condition class 1 or 2 showing substantial soil disturbance. Half of these points (and all with soil class condition rating of 1) are trails or roads. The remainder are small depressions that hold surface water or remain moist due to clayey deposits, and are trampled by livestock. Compaction and ponding of surface water are the most apparent disturbance.

Henninger Ranch

About one-half of the data points are soil condition class 1 or 2 due to compaction or soil loss. All of these points are on flat irrigated fields (points 2, 9 and 10) that have desert-like pavement, gravel surface, are highly compacted, and support little plant life other than arrowroot (*Maranta arundinacea*). Cover ranges between 70 and 95 percent in these areas. There is little slope to farmed fields, and therefore, it is plausible that soil loss is due primarily to wind erosion.

Humphrey Ranch

Disturbed areas are due to natural slumping in weakly cemented inter-bedded sandstone and silt stone. Sheep bedding areas are well vegetated, although they are compacted. The Beaver Creek floodplain/valley bottom has lush grass cover; as do all the smaller tributary valleys that support only ephemeral or disconnected flow in small incised, and loamy bank channels. The ephemeral drainage that connects with Beaver Creek, which has abundant willow growth, showed bank trampling from sheep watering along a quarter mile of the stream. The sedge meadow drainages had no observed bank disturbance.

Environmental Consequences by Alternatives

Methodology

Field observations, professional judgment, insight from the NRCS, and referenced literature were used to evaluate the potential effects.

Spatial and Temporal Context for the Effects Analysis

The spatial boundaries for soils direct, indirect and cumulative effects are the ARS properties since soil processes occur largely in-place. The spatial boundary is the ARS lands Headquarters, Henninger, Humphrey and the summer pastures.

The BLM and FS grazing allotments established, under separate NEPA documentation, the numbers of sheep and grazing period that Sheep Station is authorized/permitted to use. Therefore, direct, indirect and cumulative effects were considered, evaluated for each property, and determination made that authorized uses as potential effects, were not deemed detrimental to soil productivity. Furthermore, since the BLM and FS grazing allotments are not adjacent, connected or otherwise contiguous to one another, nor ARS lands, there could be no additive effects, thus cumulative effects, between these various properties for inclusion in this EIS.

Effects occurring within ten years are considered short term. While long-term impacts are typically greater than 10 years. Short-term impacts are considered recoverable, with regrowth established and no displacement of topsoil. For long-term impacts, vegetation is slow to re-establish, and soil is partially removed by physical displacement and/or water and wind erosion processes, with slow to limited recovery of projected productive potential.

Alternative 1 - Proposed Action (No New Federal Action)

Alternative 1 - Direct and Indirect Effects

The proposed action would continue sheep grazing and associated supporting management activities. The current soil conditions appear functional at all ARS ownerships. Bare soils are in the expected range for all areas sampled, and evidence of soil erosion is rare. Some compaction is evident on intensely used areas (e.g. around watering troughs, sheep driveways, bedding areas). However, soil properties/conditions (i.e. soil moisture, texture) for optimum compaction on lands normally grazed is minimized by dispersed use and rest rotation, limiting compaction that may be potentially detrimental to soil properties and qualities to those seasonal periods (e.g. late April to Mid-June) when soil water content/compressibility is highest. Some recovery of soil physical condition/function (e.g. unsaturated hydraulic conductivity and bulk density) can be measurable in the short-term with rotational grazing and natural processes, such as wetting and drying cycles, freeze and thaw cycles, plant root growth and decay, and soil fauna and flora activity. From a soil physical standpoint, all areas are functional and do not show overt signs of degradation.

Other effects considered are the impacts of grazing-related actions such as fence building and road-grading (see Proposed Future USSES Projects for Ground Disturbance in project file). On the Headquarters area, there are approximately 120 miles of dirt-surfaced roads, most on flat terrain and many having a gravelly surface with some vegetation on the roadway. These roads are subject to wind-blown fugitive dust, and localized sheet and rill erosion in response to intense, longer duration rainfall

events. Although these potential effects are viewed as minimal, in that fugitive dust is essentially limited due normal formation of a physical crust; dust generated by limited vehicular traffic and occasional maintenance by motor grader (< than 20 percent of road miles annually), and erosional sediment will be trapped in roadside vegetative cover or where undulating surfaces and/or litter, etc. is present to trap sediment. Soil productivity will be maintained.

In addition, about 14,000 linear feet (2.65 miles) of firebreak is maintained/rough graded by motor grader annually. About 10 acres of bare mineral soil is potentially subject to erosion from overland water flow from intense, longer duration rainfall events, and wind, as are unsurfaced roads. Likewise, about 15 acres of bare soil could be created by dozer and motor grader each year in support of the Station's prescribed annual burning program.

The overall plan is to burn Headquarters pasture areas about every 30 years, this could equal prescribed burning of approximately 900 acres each year. Actual burned area over the past 30 years, 13,867 acres, has been less than the planned average 900 acres per year.

In the next five years, the Sheep Station plans to burn 400 acres per year. However, since the burning cycle yields a return cycle of once every 30 years these acres are allowed to fully recover their vegetation cover within two to three growing seasons. Erosion and sedimentation therefore, is of low risk to soil productivity and water quality.

Indirect activities considered are range stewardship activities such as prescribed burning and treatment of noxious invasive weeds. The latter is done through a combination of targeted grazing by sheep and use of herbicides (Appendix C of the EIS).

Grazing effects

Using vegetation as an indicator of soil health, the current vegetation composition for Humphrey and the summer pastures appears stable, showing no signs of degrading range conditions. Reports on trend for the summer pastures by Klements (1997) and VanHorn-Ecret (1986) show the composition of vegetation within exclosures installed in the 1960s does not differ substantially from the composition outside exclosures. Humphrey has a strong presence of desirable native range species and approaches the expected sagebrush community type based on the NRCS range sites (SCS 1981). These conditions should persist given the long history of managed grazing by the USSES. The low utilization of six percent at Headquarters and 14 percent at Humphrey, along with the varied staging/gathering of sheep throughout the year; has resulted in the conditions observed. At Henninger, grazing use observations and higher utilization (24 percent) compared to the other properties, indicate a downward trend (see Range Report, 2009), possibly related to the altered hydrology regime from historic downcutting of Dry Creek and irrigation diversion.

Localized areas of soil disturbance associated with sheep driveways and bedding would continue to occur, though the vegetation appears stable, healthy, and robust enough to recover seasonally, and no chronic erosion is occurring. Sheep on bedgrounds generate a substantial amount of nutrients from manure and urine. In addition, bedding reduces the amount of standing vegetation and can potentially increase the amount of bare-exposed soil from disturbance, and cause some compaction. However, infiltration rates will remain high and only from a rare storm occurrence (i.e. \leq 100 year-24 hour rainfall) yielding a high intensity, long duration precipitation event, would runoff occur above background or historical occurrence, so as to potentially cause erosion damage and transport of suspended sediment, particulate matter (manure) and dissolved solids/nutrients off-site; whereby potential soil productivity and water quality would be adversely effected.

Headquarters

Soil function would continue at Headquarters with vegetation composition aligning with expected diversity and species representation (NRCS 1991, (in review)) on the shallow and moderately deep soils. Bottomlands have more divergent species mixes with a higher abundance of pasture grasses in addition to 10-15 percent of the property planted with crested wheatgrass (*Agropyron cristaetum*) to improve forage. The productive swales have an influx of exotic pasture grasses due to the richer soil fertility here. In these arid environments, higher productivity sites have a propensity for supporting exotic species (Lejuene and Seastedt 2001, Bashkin et al. 2003). Vegetation composition would persist in the Headquarters areas, although crested wheatgrass could expand.

The presence of exotic grasses such as the planted paddocks of crested wheatgrass and pasture grasses impacts the soil biotic community (Wardle et al. 2004, Wolfe and Klironomos 2005), but does not lower productivity per se. Expansion of the perennial grasses would have less impact than expansion of cheatgrass (*Bromus tectorum*) (Norton et al. 2007). Predominance of cheatgrass changes the moisture regime in soil with finer root structure and different litter quality, ultimately shifting the fertility regime to favor itself, an unwelcome departure from conditions preferred or desired for adaptations by competing native species (Belnap and Phillips 2001, Thorpe and Callaway 2005, Norton et al. 2007). Currently, cheatgrass is relatively sparse across the range; ≤ 1 percent. The presence of the exotic perennial grasses would most likely show changes in arbuscular mycorrhizal assemblages (Wardle et al. 2004) but not impact resources such as nutrients and water (Norton et al. 2007).

Henninger Ranch

Henninger shows degradation on the sage flats where conditions have departed from the expected community (see USSES Range Report. 2011; NRCS (in review)). Species composition is stable with pasture grasses and grazing increaser forb species, but lacks native grass species. The current condition shows a downward trend, although no obvious evidence of erosion was observed. Historical grazing at the site along with evidence of dewatering from entrenched drainages suggests a shift in the water table. This site also has irrigation, both at the site and from adjacent land users. The upland sage community has likely expanded into bottomland areas though the extent is uncertain.

Henninger uplands show fair conditions with plant species diverging from the historic community. The exotic perennial grass smooth brome (*Bromus inermis*) is common indicating past seeding and thus may interfere with recolonization of native grass species. Observations found that upland rocky areas where conifers and aspen predominate are closer to the expected plant assemblage. That said, this area gets higher sheep use at 24 percent utilization than all other ownerships of ARS (see Table 1). The forested upland areas are stable; soil erosion is sparse at the site.

Humphrey Ranch

Continued sheep grazing at Humphrey would not substantially change soil resources from existing conditions. This area has moderate use at 13 percent (Table 1, page 12) and the vegetation is close to the expected range for this area. Overall, vegetation is robust, diverse and soil erosion not evident outside the bare slope zones from small landslip. These bare slope areas are considered a natural feature and continue to supply water deep soils in adjacent swales below. Soil development is a century to millennium process. The very dark accumulated organics in these swales compared to much shallower adjacent hill slope soils, suggest that these slips/shallow slope failures are a natural ongoing process.

Riparian soil impacts are mixed at Humphrey. Sedge meadow soils appear intact with minimal impacts for the north tributary of Beaver creek on Humphrey. Willow sedge soils along a quarter mile of southern

Beaver Creek tributary will continue to experience seasonal impacts from sheep watering. Canada thistle and upland species along the banks here show historical grazing use at the site. Given the long history and steady grazing numbers, the conditions would likely stay the same with continued grazing.

Summer Range

Summer pastures show abundant productive capacity given the higher precipitation regime and vegetation state than on the lowland properties. Current vegetative assemblages suggest a stable vegetation community. Keith Klement found no outstanding differences for vegetation inside and outside exclosures during his 1990s sampling (1997). Sampling during summer 2009 showed vegetation within expected ranges for the sites compared to the soil surveys in the 1990s (see USSES Range Report, 2010; NRCS 1991). Given the similar management regime to the 1990s, the existing range and soil conditions would continue.

Some bare soils from annual operations were observed, but do not show chronic erosion sign. Soil disturbance from sheep drives is temporary and groundcover restored with regrowth. Past evidence of bare soils and degraded conditions is referenced (Klement 1997) and reported for Toms Creek in the middle 1980s (Montagne 1988). Bare soils are isolated and related to sheep bedding on ridges, past impacts from combination of old wildfire and/or historic grazing practices (Klement 1997), and natural bare slopes related to snow patches on protected aspects. Sheep bedding areas are typically scattered and less than one quarter acre each. The chronic erosion patch observed is one-quarter acre and continues to sheet wash. This area is not grazed. The snow slopes are steep, un-vegetated slopes and therefore experience only transient use by sheep.

Sheep impacts on the nutrient regime are most prevalent at bedding sites. A recent study by Leytem and Seefedt (2008) for sites on the USSES summer range highlights the changes. The bedding sites have reduced vegetation and this translates to lower organic carbon and long-term nitrogen (total N). The input of sheep feces offsets the lack of vegetation somewhat with spikes of ammonium ($\text{NH}_4\text{-N}$) and soluble phosphorus (P), although overall the bedding areas experience a net loss of nutrient potential (Leytem and Seefedt, 2008). The impact of these conditions can influence the vegetation at these bedding areas although specifics were not given in the study. More opportunistic vegetation is associated with these spikes (Vinton and Burke 1994) with exact characterizations dependent on grazing history and ecological context (Milchunas and Laurenroth 1993, Biondini et al. 1998).

Nutrient impacts from sheep grazing outside of the main congregation areas such as bedding areas are not expected. Areas outside of the bedding areas are well vegetated, thus shifts in nutrient cycling, due input from urine and manure would not occur. The dispersal of sheep and low utilization of available forages diminishes potential impacts.

Overall the summer pastures have likely improved from the 1980s with rest rotation instituted, elimination of one band of sheep (1,000 animals), and continued emphasis on herding for light, even use by sheep. Adaptive management principles emphasize even usage by the sheepherders and avoidance of low productivity sites. The poor conditions cited by Montagne (1988) at Toms Creek were initially monitored for grazing effects, and later closed to grazing altogether due to low availability of forage, and snow displacing the monitoring exclosure fencing (Jacobson, 2009, personal communication).

Table 1. Percent utilization with the existing proposed action (Alt 1) versus the no grazing alternatives.

Properties	AUM Available	Existing Alt1	Percent of Available AUMs used by Alternative

Invasive plants

The control of invasive plants advances soil productivity by limiting the spread of weeds capable of adversely influencing soil function/properties and qualities. The containment and eradication strategies pose risk for adverse effects from select grazing and herbicide use. Select grazing can result in overgrazing of non-target species if grazers are mismanaged. The most common herbicides used, Curtail (2,4 D), Krovar (Bromacil and Diuron), and Roundup (Glyphosate) have minimal adverse effects on soil biota, but do vary in leaching and runoff potential. Krovar has particularly high risk for offsite transport to groundwater and runoff.

Select sheep grazing and herbicide spraying are used to contain the spread of invasive plants. The main species targeted are leafy spurge (*Euphorbia esula*), spotted knapweed (*Centaurea stoebe*), and cheatgrass (*Bromus tectorum*). Minor infestations are noted for hoary cress (*Cardaria draba*), lambsquarters (*Chenopodium album*), kochia (*Bassia scoparia*) and thistle (*Cirsium spp.*). Handspraying targets roadsides, feedlots and corrals, and near building structures. Broadcast spraying is done with a four-wheeler or tractor- in small pastures and large feedlots. Aerial application is not used. Roughly, 50 acres are sprayed annually (Table 2, page 13).

The ecological, and thus soil related, implication is notable for leafy spurge, spotted knapweed, and cheatgrass. These plants are pervasive in arid rangelands. The success of these species may be due in part to positive feedbacks they create in the soils as self-sustenance, in addition to lack of predators such as soil pathogens (Thorpe and Callaway 2005, Wolf and Klironomos 2005). Cheatgrass changes soil structure and can influence nutrient content and timing (Hawkes et al. 2006, Norton et al. 2007). Spotted knapweed may “mine” phosphorus unavailable to other species (Thorpe et al. 2006) in addition to altering nutrient cycles with its root exudates (Thorpe and Callaway 2005).

Selective grazing by sheep is documented as effective for control and eradication of leafy spurge and spotted knapweed (Olson and Lacey 1994, Tu et al. 2003). Selective grazing for leafy spurge has reportedly resulted in up to 90 percent eradication (Olson and Lacey 1994), while spotted knapweed

control is mixed, probably due to the bittering agent in leaves cnicin (Whitney and Olson 2006). It would make sense that select grazing would benefit soils by moving plant community structure further toward native composition.

Herbicide treatment on the USSES lands is outlined below. The main herbicide used is Curtail which is a mix of 2,4 D and clopyralid. Roadsides and fence lines at Headquarters are the main targets for control of weed infestations with an average annual treatment of 45 acres. Secondly, Krovar – a composition of Bromacil and Diuron – is applied to the two acres of headquarters feedlots. A recent pasture reseeding at Humphrey used Roundup (Glyphosate) for 12 acres. Other herbicides with some prior use at the USSES, though not used regularly, include Arsenal (imazapyr), Tordon (picloram) and Garlon (triclopyr).

Herbicide application indirectly benefits soil function by containing the spread of noxious weeds, particularly those that alter soil nutrient regimes. Most of the spraying focuses on weed containment and eradication along travelways and high-disturbance areas such as the feedlots. Adverse impacts on soil organisms overall is not expected given the low toxicity listed by Tu et al. (2003) and using application rates within label restrictions. Decomposition of all listed herbicides is primarily by soil microbe metabolism.

However, certain suites of microbes are sensitive to Tordon (picloram), Arsenal (imazapyr) and Garlon (tryclopyr). Tordon has some toxicity to certain fungi at high application rates and is known to affect the nitrification portion of the N mineralization cycle (SERA 2003a). Garlon is toxic to some soil bacteria at low and high doses (2004). Arsenal has slight effect on soil microbes at high doses (SERA 2004).

Table 2. Herbicide general use, types and location

Herbicide	Active ingredients	Area	Frequency	Acres	Notes
Curtail	2,4 D (39%) and Clorpyralid (5%)	Headquarters roadsides +/- 5 m	Annual	35	Leaches, esp. sandy soils and shallow water tables
Curtail	2,4 D (39%) and Clorpyralid (5%)	Humphrey roadsides (+/- 5 m) and fencelines (+/- 2 m)	Annual	10	Leaches, esp. sandy soils and shallow water tables
Krovar	40% Bromacil (40%) and Diuron (40%)	Headquarters feedlots	Annual	2	leaches readily, long half-life in soil
Roundup	Glyphosate (48%)	Humphrey pasture reseeding	One time	12	Strong sorption to soil

Herbicides are typically used on disturbed areas such as roads and feedlots. These areas are characteristically compacted and barren, and may increase herbicide residence time. Soil chemical and biological processes are key to the breakdown of herbicides, so impaired conditions can lead to longer residency. Krovar and Tordon have relatively long residence times in soils, with soil half lives in the order of a year or more (Extronet 1993, SERA 2003a); while Roundup and Garlon have short residency times in soil, at 47 days (SERA 2003b) and 30 days (SERA 2004) respectively. It should be noted that these half-lives are averages and vary depending on the amount of moisture available, organic matter and warmth for soil processing (Bollag and Liu 1990).

Krovar, Tordon, and Curtail have moderate to high leaching potential and can contaminate groundwater if used near shallow aquifers (Extronet 1993, Dow 2008, Dupont 2008). Herbicide buffers are recommended to ensure adequate protection (see Protocols, Appendix A: Integrated Pest Management). Roundup has a very strong affinity to soils and thus has the least potential for affecting groundwater. Once absorbed by soils the herbicide is degraded by soil microbes and is unavailable to plants.

Prescribed Burning

Short-term adverse impacts to soils from severe burning are not expected from either fall or spring burning as fuel loads are light, resulting in fires of shorter duration and less soil heating. Nor are erosion rates predicted to increase given the low seasonal rainfall. Prescribed burning is expected to increase mineral forms of N and P in the short term (1-2 years), with long-term effects uncertain. Soil biota and productivity would be adversely affected with expansion of cheatgrass.

Prescribed fire generally increases mineralization cycles in the short-term (Fisher and Binkley 2000, Erickson and White 2008) with long-term consequences depending on the vegetation and soil biotic conditions (Hart et al. 2005). Plant available nitrogen and phosphorus increases for the first (one) year, while increases in sagebrush systems of up to four years for nitrate are reported (Rau et al. 2007). Mackenzie et al. (2006) have found elevated nitrate in nearby forested systems for up to 60 years. The effects are highly dependent on biological substrate and precipitation since mineralization is a soil biotic process (Hart et al. 2005, Rau 2007).

Cheatgrass is of particular concern with regards to changes to the soil nutrient regime and the risk of more frequent flashy fires (D'Antonio and Vitousek 1992, Norton et al. 2007). These sagebrush regimes appear sensitive to the increased fire frequency associated with cheatgrass expansion (NRCS (in review), Zouhar et al. 2008). Cheatgrass invasion is thought to occur during high moisture years and may actually decline in drought (Zouhar 2008). ARS personnel have not observed cheatgrass expansion in the mountain big sagebrush vegetation types where they are burning.

Alternative 1 – Conditions on Non-ARS Lands Used by the USSES

Of the grazing allotments/leases utilized by Sheep Station, Meyers Creek and East Beaver Creek (FS Lands) are grazed in summer to early fall when soil conditions are capable of supporting managed grazing with slight risks of adverse impacts to soil properties and qualities, particularly so with sheep numbers ranging between somewhat less than 10 percent to less than 20 percent of the authorized/permitted number by the FS, with a very light forage utilization that ranges between 2.3 and 1.2 percent respectively. On the Snakey-Kelly (FS) and Bernice (BLM property), used for winter grazing, a period when soil conditions are most favorable for protecting soil productivity (e.g. low soil moisture, thus potential compaction, and likely frozen soil in the upper soil horizons) the number of sheep are less than 20 percent of authorized/permitted numbers, and utilization is less than 25 percent of available forages. The Mud Lake property (DOE), with exception of the feedlots, is grazed during two seasonal periods, winter to early spring, and late fall. Risks to soil productivity are moderate in the spring with increasing soil moisture, but decreasing to slight as the grazing progresses; soils possess fair to good suitability under managed grazing. Utilization of available forages is below 30 percent of carrying capacity.

Alternative 1 – Cumulative Effects

ARS Properties

Grazing and associated supporting management activities, as proposed under this Alternative, would have little if any additional cumulative effects on soils

Non ARS –Lands

Since the BLM and FS allotments, and DOE Lands used for a winter feedlot and limited grazing (Mud Lake), aren't contiguous to one another, nor ARS properties, there isn't any additive effects, thus cumulative effects, between these various properties.

Furthermore, since utilization of available forages under Alternatives 2-5 would be eliminated or reduced for all allotments, with exception of the Mud Lake (DOE) feedlot, where utilization would see a very slight increase of 1 percent compared to Alternative 1, soils would remain stable and well suited for grazing, related supporting management activities, and other resource benefits and values. Thus cumulative effects would not occur, so as to be easily discernable, if at all, on non-ARS lands.

Alternatives 2-5

Alternatives 2-5 Direct and Indirect Effects

Areas of current and historical sheep grazing would continue in existing vegetation cover for both lowland Headquarters, Henninger, Humphrey and the highland summer ranges in the Centennials. Discontinuation of grazing would allow for more leaf litter available for organic accumulation and recovery of soil function in compacted areas in the long term. The no grazing alternative would not produce detectible/measurable changes on soils for Headquarters, Humphrey, or East Summer pastures since the projected use is near or less than the current 10 percent (Table 1). Soil conditions should improve at Henninger for Alternative 2, since use would be discontinued compared to the current 24 percent forage utilization, but recovery would not likely be discernible in the short-term. Alternative 3 would extend grazing through summer months on Headquarters, and boost AUMs used, but the effect is uncertain as no discernible changes are anticipated since utilization of available forages continues at less than 10 percent, and sheep grazed/acre over this large acreage would be insignificant.

Other properties would have reductions in AUMs ranging between -20 to -100 percent. On Humphrey, East Summer Range, and West Summer Range, from which all grazing would be suspended, there would be no further potential direct and indirect effects to soils, and with anticipated recovery of any areas impacted from historical grazing, as small in areal extent, and difficult as they would be to observe visually would be eliminated. Alternative 4 could have some lower recovery potential at West Summer Range without a rest rotation system, but no discernible changes in effects are projected. However, on East Summer Range where grazing would be suspended, as noted in Alternative 3 above, potential impacts, direct and indirect, would be eliminated as well. Alternative 5, given an overall 40 percent reduction in AUMs, would indicate a decrease in soil disturbance/compaction, and erosion.

Conceptually, where grazing is discontinued on lowlands, plant and soil associations would persist since the arid conditions lend to slow recovery potential. Long-term studies on sheep grazing during the mid-20th century show varied potential for recovery based on current soil potential and vegetation composition (Michunas and Laurenroth 1993, Johnson 2003). State and transition models developed for rangeland integrate these ideas and use indicator species and surface soil conditions to judge not only current condition, but also recovery or trajectory of the plant community (NRCS (in review)). Compacted staging areas for animals would stay compacted for the long term given arid conditions and the relatively infertile environment. In contrast, uplands with species compositions closer to the historic climax communities and with hydrologic regimes intact would have greater regrowth potential. For the USSSES properties on the lava plains, Henninger has the highest potential for regrowth with no grazing given the favorable climatic conditions.

The absence of sheep grazing would no doubt improve litter accumulation and retention of biomass. This cover would add mulch and further protection to soils. Plant composition changes would be difficult to detect after resting given the resilience of the current communities and the closeness to the expected natural habitat for the northern reaches of Headquarters, and especially Humphrey, using the NRCS ecological site logic. Again, the differences may be subtle given the current low uses on these lands.

Cessation of grazing would improve footslope and dry meadow sites at Henninger for Alternative 2. Henninger serves as a staging area and has utilization of 24 percent (Table 1). Henninger has higher moisture, deep soils, and lacks the calcareous upper soil layer that can limit plant production. Improvement would be most notable on the footslope sage sites. The predominant species mix of pasture grasses in the lowlands would persist and therefore a higher-level plant community state is not expected, though production could improve. In addition, the altered hydrology from irrigation and deeper entrenchment of Dry Creek has less potential to support historic dry meadow plant species.

Humphrey pasture has strong semblance to the expected native vegetative community, and, therefore, may show minute improvements except in the willow riparian area. Floodplain soils along this tributary of Beaver Creek would show improvement over the current condition if grazing were terminated, since soils have good functional attributes, albeit with some Canada thistle and upland shrubs. Compaction is rare and the current vegetation suggests good soil through-flow. Given these conditions, recovery potential is high. The collapsed banks would stabilize allowing improved movement of soil moisture outward. In addition, mesic vegetation species adjacent to the stream could establish without sheep grazing facilitating vegetation and soils recovery.

Alternative 4 would condense grazing to the West Summer range only for the summer and likely not utilize the rest rotation system. Alternatives 2 and 3 eliminate grazing for both alternatives. Alternative 5 decreases grazing proportionally to about 2/3 of current levels. No differences would be detected in the short term for alternatives 2-5. Alternative 4 could potentially generate worse seasonal range conditions with concentrated use in the West Summer range with more incidental soil damage from trampling and bedding.

Invasive Plants

Eliminating grazing and active management in Alternatives 2-5 would have uncertain impacts for invasive weeds and thus soil productivity. Eliminating selective sheep grazing and loss of active management could further expand distribution of existing invasives. On the other hand, reduced sheep numbers and associated inputs of fecal matter and disturbance, along with less travel use of road ways decreases opportunities for invasive plants and, thus, impacts to soil productivity.

Herbicide use would decline by 10 acres annually with elimination of the Humphrey range in Alternatives 2 and 3 and cease altogether except for the two acres at the USSES main facility (Table 1). No changes in soil productivity are anticipated with this reduction in use since the sprayed areas are primarily disturbed sites. The tradeoffs are similar to those for the elimination of selective grazing.

Prescribed Burning

Alternatives 3-5 would have similar impacts from prescribed burning to Alternative 1, since these alternatives retain Headquarters as primary range. The assumption is the elimination of sheep grazing at Headquarters would eliminate the burning program. For Alternative 2, eliminating the burning program reduces the opportunity to maintain the natural 25-40-year fire cycle,

Summary of Direct and Indirect Effects

Alternatives 2-5 – Changes on Non-ARS Lands Used by the USSES

Effects from continued grazing and related activities on Non-ARS Lands, supporting the mission of Sheep Station, including past, present, and foreseeable future grazing and related actions is not foreseen as detrimental to soil productivity, and/or other functions and values provided by the soil resources in the long-term

Alternatives 2-5 – Cumulative Effects

ARS Properties

Alternative 2. With elimination of grazing, there wouldn't be any further or additional cumulative effects.

Alternative 3. Cumulative effects, even with a 3.5 percent increase in forage utilization on Headquarters, would be minimal and of slight risk to soil function and values for soils under this Alternative - not easily measured or documented.

Alternative 4. Even with slight increases in forage utilization on the Henninger Ranch property (0.8 percent) and East Summer Range (2.1 percent), cumulative effects would be minimal and not easily measured or documented. Soils would remain stable for all properties, except for a slight downward trend for the Henninger property under Alternatives 3 and 4.

Alternative 5. With reduced grazing, between 30 and 40 percent, no cumulative effects would occur.

Non ARS –Lands

Because utilization of available forages under Alternatives 2-5 would be eliminated or reduced for all allotments, with exception of the Mud Lake (DOE) feedlot, where grazing utilization would see a very slight increase of 1 percent compared to Alternative 1, adverse soil effects to productive potential would be slight, and likely not measurable; retaining fair-good suitability for long-term grazing use as planned. No cumulative effects are anticipated.

Summary of Cumulative Effects

Adverse cumulative effects are not expected for any of the alternatives. Effects from the mine at Odell, wildfire and prescribed burning are not degrading soil productivity.

The additive effects of past grazing are considered more in detail within the context of the current plant community and soil condition (see Affected Environment and Direct Effects sections). Over the last 86 years, grazing management appears relatively consistent with possibly upward trends in the last twenty years from reduced grazing and rest rotation in the uplands along with evolving grazing practices.

Rehabilitation has occurred on the road to Blair Lake and to the Odell mine, returning hydrologic function. Soil impairments from soil removal would continue at the mine site (see USSES Hydrology Report, 2011) while the road to Blair lake has mixed revegetation success. Observations in summer 2009 found some sign of continued off road vehicle use. The forb-dominated vegetation was responding well due to the presence of mollic soils. Ruts were still visible in some areas with continued erosion between water bars. Reclamation at this area will depend on successfully blocking motorized travel. Adverse effects are limited to the road area and thus isolated.

Historic wildfire could continue to affect soil productivity on USSES lands on the summer range. Wildfire effects from the early 1900s remain visible in the East Summer range, with old erosion gullies still observed on the north side of Toms Creek divide. This is indicative of the low productive soils forming from interbedded dolomitic limestone and shale on steep slopes. Elsewhere, evidence of old wildfires aren't visible, and soils stable and vegetation robust. Recent fire on the Meyers Creek allotment shows quick recovery.

Prescribed fire is limited to the Headquarters range where ongoing efforts continue. Roughly 19,000 acres have burned since 1936. About 70 percent of this is from wildfire, though a more active burning program has been in place over the past 10 years; with prescribed burning averaging 600 acres per year. The USSES would like to increase to 900 acres per year to approximate a natural 30-year fire-return interval. Positive effects occur where fire is returned to the system through nutrient influx. Adverse effects occur where cheatgrass increases.

Alternatives 1-5 Summary of Effects

Table 3. Summary of soil effects: A comparison of direct/indirect and cumulative effects by alternative.

Soil Effects	Alternative 1	Alternative 2	Alternative 3	Alternative 4	Alternative 5
Grazing					
Agricultural Research Service Properties					
Headquarters	Stable	Slight improvement with added leaf litter	Stable		
Henninger	Downward trend from decreased plant vigor, litter production	Improvement on lowland and footslopes with higher litter, less disturbance	Downward trend	Downward trend	Slight improvement with less grazing use
Humphrey	Stable	Improvement in Beaver Creek riparian soils	Improvement in Beaver Creek riparian soils	Stable	Stable
Summer Range	Stable	Slight improvement with added leaf litter	Slight improvement with added leaf litter	Risk for downward trend in summer west from no rest-rotation	Slight improvement with added leaf litter
Leased total (DOE, USDA-FS, DOI-BLM)					
Mud Lake	Stable	Improvement	Stable		
Snakey-Kelly	Stable	Improvement	Stable		Improvement
East Beaver	Stable	Improvement	Improvement	Stable	
Meyers Creek	Stable	Improvement	Improvement	Stable	
Bernice	Stable	Improvement			Improvement
Other Activities					
Invasive Plants	Decreases risk of invasion, possible offsite leaching of krovar	Uncertain: eliminates grazing weed dispersal, decreases active control	Decreases risk of invasion, possible offsite leaching of krovar		
Prescribed burning	Mimics fire cycle, increases cheatgrass spread risk	Tradeoff: Lowers cheat grass risk and active burning program	Mimics fire cycle, increases cheatgrass spread risk		

Irreversible and Irrecoverable Commitment of Soil Resources

No irreversible commitments of soil resources, on USESS properties, under all alternatives considered, are recognized; where potential soil productivity/full function has been destroyed or only recoverable over extremely long periods. There are areas where productive potentials are considered irretrievable, where soils have been committed to, or restricted for other uses (e.g. annually maintained firebreaks, roads, sheep driveways). This represents a management decision to restrict use and management of those lands for other purposes, but those decisions/actions are not irreversible. They represent a commitment of soil resources necessary to support the overall research mission established by executive order and public law for Sheep Station, through use and management as proposed in each alternative. Potential impacts to soil productivity have been recognized, but those impacts aren't irreversible; impacted soils can be managed and/or restored to achieve full benefits, functions and values.
