Researchers at the USDA/ARS Northern Plains Agricultural Research Laboratory in Sidney, MT, including Bob Evans (agricultural engineer), Bill Iversen (physical scientist), and Bart Stevens (agronomist) as well as other scientists at the location initiated a five year strip till study in Fall 2003 for the 2004 season on sugarbeet following small grains grown under sprinkler irrigation (1st phase ends 2009). They now have four years of data. Some preliminary results and observations are presented below.

**Abstract**: A project to evaluate new technologies for strip tillage of small seeded crops was initiated in fall 2003 near Sidney, Montana for sprinkler irrigated sugarbeet (*Beta vulgaris L.*) to be grown in 2004. Treatments were compared to conventional grower practices in fifty-six 15 m by 25 m (48 ft by 80 ft) side-by-side plots. Both treatments were flat planted with no ridges or beds. All tillage and fertilization was done in the fall after removal of a malt barley crop. Thirty centimeter (12 inch) wide strips were tilled directly into the straw residues about 20 cm (8 inches) deep using straight and paired fluted coulters and a modified parabolic ripping shank followed by a crows-foot packer wheel. Toothed-wheel row cleaners are in front of the straight coulter to move loose residue to the side. At the same time, dry fertilizer was shanked (banded) in about 5 cm (2 in.) below and to the side of the future seed placement. Beets were planted about 2.5 cm (1 in.) deep on 60 cm (24 in.) rows in the spring. Toothed-wheel row cleaners are also in front of each row on the planter to move any residue displaced by winter storms. Operation of the strip tiller required about 25 tractor horsepower per row, but substantial fuel savings are realized with this system by greatly reducing the number of tractor field passes. In 2004, 2006 and 2007 there were no significant differences in yields or sugar production between the two tillage treatments; however, in 2005 the strip tilled plots produced about 17% greater yields (tonnage and sugar). This benefit was primarily due to the standing straw stubble in the strip tilled plots that protected sugarbeet seedlings from blowing soil during a spring wind storm that severely damaged seedlings in the conventionally tilled plots where there was no surface crop residue. Banding fertilizer is highly recommended to increase fertilizer use efficiencies and reduce input costs. RTK-GPS guided steering is recommended when fertilizer is banded into the row. Heavy soils seem to work better when strip tilled in the fall whereas lighter, sandy soils can be strip tilled in the spring and combined with planting into a single pass. Strip tillage must be considered as part of a larger cropping system that affects timing and equipment choices for planting, cultivation, spraying, and harvesting as well as tillage and other practices: it’s not just a matter of adding one new piece of equipment.

**Key Words**: Conservation tillage, zone till, inter-till, soil erosion, crop residue.
INTRODUCTION

Strip tillage (sometimes called zone tillage or inter-till) is widely used in rainfed areas in the Midwest U.S.A. on large seeded crops like corn (*Zea mays* L.), soybeans (*Glycine max* (L.) Merr.) and cotton (*Gossypium species*) (e.g., Janssen et al., 2005; Smith et al., 2002; Al-Kaisi and Licht, 2004; Niehues et al., 2004). However, development of strip tillage for small seeded crops like sugarbeet (*Beta vulgaris* L.) has been slow, but that is rapidly changing with the advent of Roundup Ready® cultivars and the high price of diesel fuel.

By some definitions, strip tillage is a method that tills a relatively narrow strip (e.g., 20 to 30 cm [8 to 12 in.] wide) into existing crop residues at a relatively shallow depth (e.g., ≤ 7.5 cm [3 in.]) covering 25% to 50% of the surface area. Zone tillage, on the other hand, often refers to technologies that till similar strips, but are deeper than 7.5 cm. In this paper, we are using strip tillage as a general term even though we are tilling in the 20 cm (8 in.) deep range because of term’s wider usage among growers and industry when referring to all of these technologies.

There are currently about twenty different manufacturers of strip till equipment, and most of these have been developed for corn and soybean culture. Most of the currently available strip till machines use spherical or conical disks to loosen the soil and prepare the seedbed. Many also use some type of shank or ripper to help loosen the soil and to apply liquid or dry fertilizer either to the side or below the seed bed. Many machines have some sort of packer wheels or baskets to re-firm the tilled soil, break up large clods and do some minor surface shaping of the strip. Several of the disk- or coulter-based till systems tend to place soil over the residue with limited mixing of the residue, and others may not adequately repack the strip to create a firm seedbed or re-close the ripper slot. However, a major concern is that many of these machines generally don’t make a firm enough bed for small seeded crops like sugarbeet where good seed-soil contact is critical and even nearby small air pockets must be avoided. Furthermore, seedlings of tap rooted crops like sugarbeet often have difficulty penetrating buried residue layers.

The overall goal of this research was to develop and test a strip till system that was suitable for small seeded crops after small grains. The primary hypothesis of this research is that strip tillage of sugarbeet after spring grain under sprinkler irrigation will produce yields and quality at least equal to conventional tillage practices while saving fuel and time, and reducing wind erosion of soils. The specific objectives were:

- To develop and evaluate a prototype strip tiller and banded fertilizer application system suitable for small seeded crops such as sugarbeet after small grains.
- To develop a set of experiments to compare conventional tillage and strip till under sprinkler irrigation on yields and quality of both sugarbeet and malting barley (*Hordeum vulgare* L.).

This type of information is solely provided to assist the reader in better understanding the scope of the research and its results.
• To develop a cultural system for two year sugarbeet rotations based on strip tillage in high levels of small grain residue, and that relies on a grower’s existing equipment as much as possible.

While not reported in this manuscript, this multidisciplinary, irrigated cropping systems research project is also comparing soil properties, nitrogen/carbon cycling, N-fertility placement and amounts, incidence of foliar diseases, soil erosion from wind, soil compaction and conservation of soil moisture between strip till and conventional tillage treatments.

**Previous Strip Tillage Research on Sugarbeet**

There has been strong interest in conservation tillage techniques, mostly looking at some type of strip till, for sugarbeet for many years (i.e., Simmons and Dotzenko, 1975; Fornstrom and Boehnke, 1976; Glenn and Dotzenko, 1978; Sojka et al., 1980; Halvorson and Hartman, 1980, 1984, 1988; Giles et al., 1982; Deibert et al., 1982; Miller and Dexter, 1982; Adams, 1988; Smith et al., 2002). However, relatively little work has been done on strip tillage of sugarbeet over the last 20 to 25 years for both practical and technical reasons that will be explored below, although its potential has been widely recognized.

Pervious strip till work on sugarbeet at Sidney, Montana used multiple-row, narrow rototiller type devices to make 18 cm (7-inch) strips in the grain stubble on heavy clay soils to obtain the necessary type of seedbed (Halvorson and Hartman, 1984, 1988). The following discussion in this section reviews some of this research.

While relatively successful, this work was not generally adopted by growers for a number of reasons. The system required plowing, mulching, leveling and bedding of the field prior to the planting of the small grain crop in the year before the sugarbeet crop was planted. In the early 80s there was very little overhead irrigation in the lower Yellowstone Valley region, so the researchers developed a system that could be used with furrow irrigation.

The challenge of creating a sufficient furrow to irrigate the beets the following year was addressed by creating a raised bed before the grain was planted and not disturbing it prior to strip tilling. There was also no need to obliterate border dikes which were no longer needed to irrigate the grain if the furrows were in place prior to strip till. This necessitated a change in how small grains were typically irrigated, which now required a siphon tube in every row instead of the simpler and more common practice of a few holes cut into an earthen ditch between border dikes.

Practically, it was fairly difficult not to deform the beds during the harvest of the small grain crop and the subsequent removal of the straw bales which this method required. If the soil was very dry, the beds stood up to the traffic quite well, but if the soil was somewhat moist a combine with a full hopper could flatten the bed tops to the furrow level. The cut straw was also removed, which was time consuming because traffic had to be restricted to the direction of travel parallel to the beds, and the tires used on the balers and loader tractors didn’t always fit the predetermined row spacing. Problems created by the deformation of the bed-furrow structure weren’t usually apparent until the following year when the beets were planted. If the beds were compacted by field operations prior to the strip tillage, the tiller tines would not adequately till the area where the beets were to be planted so stand establishment could be compromised. A row
crop cultivator for high surface residue conditions was not available to the researchers, so the rototiller strip tiller was also used in the furrows between the planted strips for the first cultivation. It was hoped that the tiler would chop and incorporate the residue sufficiently to allow the use of a conventional row crop cultivator for the following cultivations. Hoods over the tiler tines were supposed to contain the tilled soil, but low spots in the beds caused by the previous year’s traffic would often cause the beets to be covered with soil creating some problems with young sugarbeet seedlings. Weed escapes on the shoulder of the deformed beds were common. The second cultivation could be tedious due to plugging caused by the excessive straw residue.

Fertilizer was broadcast in the fall for these early strip till trials. Thus, only the fertilizer that was in the path of the 18 cm (7 inch) tilled strip was incorporated. In order to minimize the loss of nutrients from the fertilizer (ammonium nitrate and monoammonium phosphate) left on the soil surface, the researchers delayed the application until late fall when air and soil temperatures were lower. (However, ammonium nitrate is no longer generally available, and highly volatile urea nitrogen fertilizer is not recommended for unincorporated broadcast applications.) If it rained before the strip tillage operation was completed, it was impossible to strip till a moist clay loam soil with the straw residues because the tiler hoods would quickly become clogged. It could take up to two weeks for the soil to dry out so the operation could be completed. On a farm scale operation, this could put the grower in a situation where the strip tillage would not be completed before the soil froze. The wet soil problem would most likely be exacerbated in the spring causing delayed planting. In addition, spring tillage would negate many of the soil mellowing benefits in the seedbed due to freeze-thaw cycles during the winter on heavier soils.

This system also presented some other practical problems if the crop had to be irrigated to facilitate seed germination in the spring. For example, in 1981, a frost on May 8th killed the sugarbeet in all plots (Halvorson and Hartman, 1984). The beets were reseeded on May 12th but had to be sprinkler irrigated using handlines to achieve good germination. Most commercial growers in the area would not have had this option. Furrow irrigation was not practical in this case because the grain stubble in the furrows restricted water flow so that the water tended to overflow the furrows and run down the soft tilled strips where the sugarbeet seed was planted, washing out the seeds.

Growers were also discouraged by the high equipment maintenance and low field speeds inherent in rotary tillers, poor weed control, and frustration with residue buildup when cultivating. In addition, the difficulty experienced when harvesting sugarbeet in muddy conditions on clay soils was enhanced by the straw residue that was still present at harvest time in significant although not highly visible quantities. Consequently, if an appreciable amount of precipitation was received during harvest, instead of just the usual muddy field condition difficulties, the straw would bind with the mud and cling to the cleaning rolls on the harvester until they built up to a diameter large enough to rub against each other and activate the slip clutches. The mud and straw could also form balls in the linked chain. These did not happen with conventional tillage under the same moisture conditions and most growers preferred to stay with older tried and trusted methods, thus abandoning strip tillage until it could be refined.

Despite these perceived and demonstrated shortcomings, the promise of reduced wind erosion without a reduction in yields encouraged two area sugarbeet growers to further experiment with
Strip tillage was implemented to eliminate the extensive tillage before planting the small grain crop and attempting to band fertilizer. However, by the mid-1990s, these efforts were largely abandoned in the Lower Yellowstone Valley. Nevertheless, high grower interest in strip tillage for sugarbeet from Canada to Colorado has continued because of the large potential advantages in reducing production costs and wind erosion.

**Conventional Sugarbeet Rotations**

Sugarbeet in the lower Yellowstone Valley region are typically grown in a two-year rotation alternating with spring grains. Normally, a sugarbeet grower in the “MonDak” area of eastern Montana and western North Dakota (as well as most other sugarbeet producing areas) will make five or more passes across a field for fertilizer applications, disk plowing, leveling (1 to 2 times), mulching and hilling, all in the fall preceding the sugarbeet crop. These fuel-intensive operations are often the same for sprinkler as well as furrow irrigated fields, but some such as the leveling are not really necessary for sprinklers unless the field had been moldboard plowed, but are done to prepare a smooth seedbed following the aggressive tillage and to fill in tower tire tracks. In addition, the hilling or bedding operation is often required to meet a farmer’s USDA farm conservation plan on highly wind-erodible soils (based on the effects from traditional, multi-pass tillage practices). Flat planting sugarbeet after a small grain crop may be more practical if wind erosion can be controlled by residues or other means. In addition, the high prices of diesel fuel are making this land preparation system unsustainable (2008 production costs in the Lower Yellowstone Valley region are estimated to be about $2,200 per hectare ($900/ac) for sugarbeet due to the high fertilizer, chemical and fuel costs.)

Tillage for sugarbeet is done in the fall following common grower practice in the area because the time window to complete all spring operations is quite compressed due to high probability for rain and cold soils. In addition, this also allows any clods in the well tilled fields time to breakdown by freeze-thaw cycles during the fall and winter.

In addition, there is an increasing amount of sugarbeet production under self-propelled center pivot irrigation due to reduced labor availability and other considerations, and the strip tillage techniques should work well under sprinkler irrigation. Flat planting sugarbeet was included in this study because it would work well under sprinklers; however, it should also be possible under furrow irrigation (a topic of future research and some growers are already doing this). Flat planting with standing stubble combined with the tilled strips should provide the same or increased benefits of wind erosion control and improved soil water levels at the surface as the commonly used bedding system.

The recent addition of an elevator facility by Busch Agricultural Resources, Inc. has made six-row malting barley the primary spring grain, replacing spring wheat in many operations. Surface irrigation techniques are the most common methods of water application. The small grains are typically grown in borders whereas the sugarbeet are typically furrow irrigated.

**Current Strip Tillage Research on Sugarbeet**

Although there has been no single great breakthrough, several advances in herbicides, irrigation technologies, tillage and planting equipment, and the success of strip tillage for large seeded
crops have given rise to the idea that many of the difficulties faced by earlier attempts with sugarbeet could be overcome, and the potential benefits made it worth another look. To our knowledge, there are currently (in 2008) four locations, using various equipment types and having different objectives, where strip tillage of sugarbeet is being investigated: North Dakota State University, Fargo, ND; University of Nebraska, Scottsbluff, NE; USDA-ARS, Kimberly, ID; and USDA-ARS, Sidney, MT. Researchers in three of these locations are working on single soil types in their areas whereas the work in Sidney, MT is being done on both heavy clay loam and on sandy loam soils.

We believe that it would be advantageous to have a strip tillage machine that would also shank in banded fertilizer (reduce fertilizer losses) and incorporate the residue in the strip while providing a firm seedbed. The remaining standing stubble would also protect the crop seedlings from damage due to wind-blown soil particles. An important consideration was that reducing machinery passes from between five and seven down to one would provide substantial fuel savings. It was expected that there should also be some water conservation benefits in more uniform trapping of snow and reduced soil evaporation where residue protects the soil surface. Furthermore, it was hoped that the research and development of strip tillage systems would make irrigated sugarbeet rotations eligible for USDA conservation programs such as CSP, as well as an acceptable practice for required NRCS farm conservation plans.

**Equipment**

A review of literature on available equipment and some site visits to observe some in the field failed to find a strip tiller that the authors believed would provide an adequate seedbed for small seeded crops after small grains. Thus, the Sidney-based research used a custom-built, six-row strip tiller (Schlagel Mfg., Torrington, WY) with a 60 cm (24 inch) row spacing that leaves alternating strips of tilled and untilled small grain residue. The machine tilled a 30 cm (12 inch) strip and leaves 30 cm (12 inch) standing stubble rows in between each tilled row. The strip tillage system was designed to eliminate unnecessary tillage operations by accomplishing the same objectives in one pass as conventional operations, but with substantial savings in time and fuel.

The strip till machine (Figure 1) was designed so that it doesn’t bury the straw in a layer, but mixes it with the soil within each strip. Each row of the tiller has a single straight coulter centered in front to cut through residue. A semi-parabolic ripper shank is located immediately behind the straight coulters to lift and break up the soil (about 20 cm [8 inch] depth).

All the dry fertilizer was placed in a band during the same operation. A fertilizer tube and a “shoe” is located on the back of each ripper shank to deposit dry fertilizer about 7.5 cm (3 inches) directly below where the seed would be placed, although some fertilizer also dribbles to the bottom of the tilled zone. The depth of fertilizer application can be changed by moving the fertilizer shoe up or down on the ripper shank. The shank is followed by two angled-in fluted coulters that cut the sides of the strip, mix the residue into the soil, and help squeeze the soil to close the ripper slot to form the seed bed. Two “crows-foot” packer wheels then compact the seed bed strip. These packer wheels carry all the weight of each tiller assembly, about 240 kg (600 lbs) of down force on each strip during the operation. This helps ensure the firm seed bed required for sugarbeet seed and breaks up some of the larger clods. Experience has shown that
operation of the strip tiller for the 30 cm (12 in.) width and 20 cm (8 in.) depth requires about 25 tractor horsepower (HP) per row so tractor size is important (front wheel assist or tracked tractors seem to work well). Narrow strips or shallower tillage would likely reduce tractor horsepower requirements. Figure 2 shows the tiller in operation.

A simple mechanical guidance system was added to the strip tiller in 2005 to facilitate spring planting operations. Single fluted vertical coulters were mounted on the front bar of the strip till machine to slice the residue immediately behind each of the rear tractor wheels (same spacing as spring planting). Next a bull-tongue chisel cut a shallow, narrow furrow that was followed by rolling 50 cm (20 in.) cone-wheels that formed a small v-shaped ditch that could be used to guide mono-rib tires on the planting tractor in the spring. The fluted coulters were removed in the clay soils if the ground was found to be too wet. The same type and size cone wheels were also placed on the planter to match the mono-rib tire spacing. This has worked well to keep the planter centered in the tilled strip and ensure that the seed was in the right proximity to the previously banded fertilizer. An RTK-GPS auto-steer system has been purchased and will be used for the 2008 crop year; however, it is expected that guidance furrows may still be required to keep the planter on the row (eliminate drafting by the planter).
Fertilizer Box. A divided, gravity feed fertilizer box was added to the strip tiller in 2003 to enable one-pass operation. Application rates are controlled by two ground driven a Model Y1 Zero-Max Adjustable speed drives (Zero-Max, Plymouth, MN; http://www.zeromax.com/products/drives/drivesmain.asp), which are infinitely adjustable over their operational range. Amazone metering cups (Amazone Farm Machinery Ltd., Brandon, Manitoba, Canada R7A 6N2) are used to meter fertilizer into the tubes. These cups can be used for either seed or fertilizer, and calibration and spot testing showed them to be accurate and repeatable.

Figure 2. Picture of the strip tiller in operation with the direction of travel to the left.

Experimental Design

Research including strip tillage of sugarbeet into barley stubble has been conducted at two sites on two different soil types. These include the Montana State University (MSU) Eastern Agricultural Research Center (EARC) farm (4 ha [10 ac]) on clay loam soils with a shallow water table (e.g., 1.2 m [4 ft]) near Sidney, MT (47.7255 N, 104.1514 W), and the North Dakota State University “Mon-Dak Irrigation Research and Development Project Farm” (Nesson) in the Nesson Valley (16 ha [40 ac]) in North Dakota (48.09N, 103.06W, about 120 km ENE of Sidney) on sandy loam soils and a deep water table (e.g., 30 m [100 ft]). Table 1 presents the total rainfall and irrigation amounts for 2004, 2005, 2006 and 2007 for Sidney and Nesson Valley. All tillage and fertilizer applications are done in the fall at Sidney (heavy soils). Fertilizers are shanked into the soil in the fall strip till plots at the Nesson site (sandy soils) whereas conventional tillage and fertilization is done in the spring because of wind erosion concerns. Nitrogen fertility is supplemented as needed through the sprinkler irrigation system during the season based on petiole analyses. Soil water levels are monitored continuously with various automated sensors in selected plots, in addition to weekly neutron probe readings in every plot.

Sugarbeet (cv. ACH 927 large bare, American Crystal Co., Eden Prairie, MN) were planted at 135,000 seeds ha⁻¹ (55,000 seeds ac⁻¹) at a 60 cm (24 inch) row spacing to a depth of about 2.5 cm (1 inch). All sugarbeet plots were planted on the same date using the same equipment. In
2004 planting was done with a Heath unit planter (Arts-Way Mfg. Co., Armstrong, IA), and in 2005-2007, the planting was done with a new John Deere 1700 MaxEmergePlus machine equipped with toothed-wheel row cleaners (John Deere, Moline, IL).

Certified malt barley (cv. Tradition, Busch Agricultural Resources, Inc., West Fargo, ND) was seeded at 90 kg ha\(^{-1}\) (80 lbs ac\(^{-1}\)) at a 20 cm (8 inch) row spacing to a depth of about 3.8 cm (1.5 inches) using a small grain drill. All barley plots were planted on the same date using the same equipment.

![Figure 3. Photograph of the adjustable Amazone metering cup arrangement on the fertilizer box.](image)

Most strip tillage in the Midwest is done in the spring with banded liquid fertilizers, whereas fall tillage and banding dry fertilizers were used in this study. Dry fertilizers are used by almost all growers in the area, and were used in this study to have the same type of fertilizers in both treatments. All fertilizer for the conventionally tilled plots were broadcast whereas, as part of the one pass process, all the strip tilled fertilizer was shanked into the soil in narrow bands and the soil packed to minimize nitrogen volatilization losses as well as reduce nitrogen tie up by residues. In 2003 (for the 2004 crop year), most of the fertilizer appeared to end up in the bottom of the ripper slot, about 8 inches (20 cm) deep. The fertilizer tube and placement shoe on the ripper shank were modified in 2004, and the fertilizer was placed about 7.5 cm (3 in.) below the soil surface although probably about half still ended up near the bottom of the ripper slot for the 2005-2007 seasons.

Nitrogen and P fertilizers (as urea and monoammonium phosphate, respectively), were based on the soil test results and crop requirement. For sugarbeet, enough N fertilizer was applied so that the sum of fertilizer and plant-available soil nitrate-N was 185 kg N ha\(^{-1}\) (165 lb ac\(^{-1}\)), resulting in N application rates varying from 108 to 146 kg N ha\(^{-1}\) (97 to 130 lb ac\(^{-1}\)) at Sidney and from to 135 kg N ha\(^{-1}\) (to 120 lb ac\(^{-1}\)) at Nesson Valley. Phosphorus was applied each year at a rate of 56 kg P\(_2\)O\(_5\) ha\(^{-1}\) at Sidney and 168 kg P\(_2\)O\(_5\) ha\(^{-1}\) at Nesson Valley. The higher amount was applied at the latter location to build up the available P from an initial level of 5.6 mg kg\(^{-1}\) bicarbonate-extractable P. Nitrogen application rates were based on an algorithm provided by the sugar
company (Sidney Sugars, Inc.), which contracted the sugarbeet, and P application rates were based on recommendations published by Montana State University for furrow irrigated sugarbeet. For barley, N fertilizer was applied so that the sum of fertilizer and plant-available soil nitrate-N was equal to 0.025 kg N per kg (1.2 lb N per bu) of expected yield, resulting in N application rates ranging from 86 to 108 kg N ha\(^{-1}\) (77 to 96 lb ac\(^{-1}\)) at Sidney and from 101 to 115 kg N ha\(^{-1}\) (90 to 103 lb ac\(^{-1}\)) at Nesson Valley. Potassium (KCl) was added as indicated by fall soil test results to maintain adequate levels for sugarbeet production (>200 ppm soil test). All plots of each crop were fertilized and planted at the same times with the same equipment, respectively.

Both strip till and conventional till were cultivated twice during the season, once at about the 6 leaf stage and a second time just prior to full canopy development. A high trash cultivator (H&S, Stephen, MN) with rolling disk shields was used to keep residue and soil off the sugarbeet seedlings only during the first cultivation.

After combine harvesting, the standing stubble was 18 to 20 cm (6 to 8 inches) high. A straw and chaff spreader on the combine evenly distributed the residue over the area. All barley straw and residues were left in the field so there was a mix of standing and flat residue. The net result was that these plots had much higher levels of “trash” than would normally be encountered because most growers in the area bale the straw and remove it from the field. This was the most difficult condition, and it is assumed that if strip tillage is successful under these conditions, it should certainly work for those who remove the straw.

Both the EARC and Nesson Valley locations utilized an off-the-shelf programmable logic controller (PLC) interfaced with a custom-built, site-specific irrigation system on a self-propelled linear move sprinkler system. Depending on the research site and the objectives, either the water application method and/or application depths can be varied in 15 m (50 ft) wide bands with plot lengths greater than 5 m (15 ft) depending on the treatment and field location of each plot as the self-propelled machines travel across the field (Evans and Iversen, 2005).

Both self-propelled linear move irrigation systems use a buried wire alignment system (with the antennas located in the middle of the machine) that guides the system through the plot area. Nominal operating pressure is about 250 kPa (35 psi) and maximum ground speed is 2.1 m min\(^{-1}\) (7 ft min\(^{-1}\)) at the 100% setting for both machines.

**Sidney.** The experiments at Sidney, Montana were conducted under a self-propelled linear move sprinkler irrigation system starting with the 2004 growing season. This research is examining the interaction between irrigation method and tillage on two-year sugarbeet-malt barley crop rotations. The soil is a relatively heavy Savage clay loam (fine, smectitic, frigid Vertic Argiustolls) with sand content of 209 g kg\(^{-1}\), silt 463 g kg\(^{-1}\), and clay 328 g kg\(^{-1}\), soil pH is 7.8, soil organic C 8.9 g kg\(^{-1}\), and total soil N is around 0.65 g kg\(^{-1}\) at the 0 to 20 cm depth. Growing season average monthly air temperature from April to September 2004 ranged from 7 to 21°C.

The Sidney site-specific self-propelled linear move sprinkler irrigation system consists of five 48.8-m (160 ft) spans and a center span of 47.5 m (156 ft). The four hectare field was laid out in 14 strips 15 m (50 ft) wide in the direction of travel (56 plots). Each 15-m wide plot was irrigated by a linear move sprinkler irrigation system with either mid-elevation spray application (MESA, the most common method in region) heads about 1 m from the canopy and 3 m (10 ft) apart, or low energy precision application (LEPA) heads (Lyle and Bordovsky, 1981, 1983, 1995; Bordovsky et al., 1992; Bordovsky and Lyle, 1996; and Bordovsky and Lascano, 2003) spaced every 1.2 m (48 in.) that apply water (bubbler) about 15 cm (6 in.) above the soil surface between every other crop row (60 cm [24 in.] row widths) without wetting the canopy. Each strip was divided into four plots with two plots being irrigated with MESA and two with LEPA that were blocked by replication. Equivalent depths of water were applied for both irrigation methods.

The experiment was designed as a four year study (2 full rotations) of a sugarbeet-malting barley system. Strip till is directly compared with conventional tillage (control). Any major tillage occurs only after sugarbeet are harvested but before small grains are planted. Pest control programs are kept the same as much as possible between treatments.

The entire plot area was planted to sugarbeet in 2002 and malt barley in 2003. The linear move sprinkler irrigation system was installed in the spring of 2003, and because all the plot area was sprinkler irrigated and furrows were not needed, all the plots were flat-planted and ridges were not used even for conventional till. There were no special soil preparations other than the zone tillage operation to accommodate the strip tilled beets.

Starting in 2003, tillage for both treatments was done after barley harvest (August-early September) to prepare for the 2004 season. Conventional tillage operations were performed after broadcasting the fertilizer. The sequence of operations in all years for the conventional
treatments consisted of tilling the soil with a ripper (Case IH, Racine, WI) to a depth of about 23 cm (9 inches), 2 passes with a rolling mulcher (Brillion Inc., Brillion, WI), and 2 passes with a leveler (Eversman, Denver, CO). The following spring, a single pass was made with an S-tine cultivator equipped with rolling baskets (Kongskilde Mfg., Soro, Denmark) prior to planting.

**Nesson.** The Nesson project is on Lihen sandy loam soils (sandy, mixed, frigid Entic Haplustoll) consisting of very deep, well- or somewhat excessively-drained soil. Particle size distribution analysis of grid soil samples across the plots indicated the textural class of the surface horizon (0 - 30 cm) to be consistently within the sandy loam classification. The amount of sand, silt, and clay in the soil at 0 - 30 cm depth ranged from 640 to 674, 176 to 184, and 150 to 166 g kg⁻¹, respectively. Soil bulk density at 0 - 30 cm depth ranged from 1.51 to 1.66 Mg m⁻³. Field-saturated hydraulic conductivity ranged from 10.4 to 31.5 mm h⁻¹ at 0 – 30 cm depth.

The Nesson strip tillage work is focused on evaluating irrigation frequency and three year sugarbeet-malt barley-potato crop rotations under a self-propelled linear move sprinkler irrigation system covering about 4 ha (10 ac). These plots utilized the same planning, tillage and cultivation equipment used in Sidney.

The Nesson site-specific self-propelled linear move sprinkler irrigation system consists of eight 48.8-m (160 ft) spans and a center span of 47.5 m (156 ft). There are 19 15m (50ft) wide strips along the length of the machine set up for site-specific irrigation. Each 15-m wide set of plots was irrigated by mid-elevation spray application (MESA) sprinkler heads spaced every 1.5 m (5 ft) and fitted with Senninger LDN nozzles (#12) and 69-kpa (10 psi) regulators. The nozzles are about 1.07 m (42 in.) above the ground on flexible drops with 0.9-kg (2 lb) weights above each regulator.

Land preparation for the Nesson project started in fall 2004 and the first irrigated crops planted in 2005. Strip till on sugarbeet started in fall 2005 for the 2006 season because there was no small grain stubble present on the site in the fall of 2004. There were three crop sequences with two irrigation frequencies and six replications in a stripped-randomized complete block design (72 plots, each 15 m × 60 m) with all components of each sequence present every year. All sugarbeet at the Nesson site were strip tilled (not a treatment) into barley stubble.

**RESULTS AND DISCUSSION**

The results reported herein are preliminary. No significant yield differences for either the sugarbeet or barley were observed between the LEPA and MESA irrigation treatments in the four years of this study (2004, 2005, 2006 and 2007). The malt barley crops in all years yielded in the range of 5400-6400 kg ha⁻¹ (100-120 bushel ac⁻¹), and exceeded all the malting requirements for acceptance. Sugarbeet were all early harvested in late September so that tonnage and sucrose content are slightly lower that what most growers would experience with a later harvest date.

Observations have shown that beets planted in strip till situations have consistently germinated and sprouted earlier than the conventional beets. It has also been observed that the strip till method results in more uniform and deeper snow catch, thus retaining more moisture than the
conventional method. This additional soil water is likely the cause of the more uniform and earlier germination.

Tables 2 and 3 present summaries of the strip till and conventional till yield and quality averaged across all plots for the sugarbeet plots at Sidney (four years) and in the Nesson Valley (2 years). The only year with a significant difference in sugarbeet yield and sucrose yield per hectare for Sidney was 2005 and that difference was due an early season wind storm that heavily damaged the conventional plots while the strip tilled plots were not affected. Basically, these data show that there are no significant differences in either yield or quality between the conventional and strip till sugarbeet in terms of production; however, the reduced equipment trips with strip till should greatly lower input costs for fuel.

The generally slightly higher sucrose yield per hectare of strip till that was observed in this work compared to conventional tillage was also found in other strip tillage research (Sojka et al, 1980; Halverson and Hartman, 1980, 1984). There were no statistical differences in percent sucrose, but sugarbeet yields were often slightly higher in the strip till. It is speculated that this is related
to earlier nitrogen fertilizer uptake in the strip till resulting in the higher sugar content because those beets ran out of soil nitrogen earlier. Research was initiated in 2006 to test this hypothesis.

The percent sucrose was significantly lower for both tillage treatments in 2006 than in other years, and the strip till was slightly lower than the conventional. The low sucrose levels were common in the area and were likely due to the cooler than normal summer that caused the sugarbeet to still have excess soil nitrogen available late in the season for both tillage treatments, and the strip tilled sugarbeet appeared to be growing more vigorously later in the 2006 season than the conventional sugarbeet.

The effectiveness of strip tillage in preventing wind erosion was demonstrated in the spring of 2005. There were four sets of sugarbeet plots side by side, each set containing one plot of conventional tillage and one planted in strip till. The beets were planted in mid April and were in the 4 leaf stage in mid May when a high wind event occurred. The blowing soil severely damaged the leaves on the young beets in all the conventional tillage plots, whereas the young beets in all strip tilled plots had no visible damage. The beets in the strip tilled plots were apparently protected from the blowing soil particles by the strips of standing stubble between rows, even in side-by-side conventional and strip till plots. Fortunately, cool weather conditions after the wind storm allowed most of the conventional beets to re-grow so replanting was not required, but it delayed them sufficiently such that there were significant yield differences in the fall.

The average number of sugarbeet per 3.3 m (10 ft) of row over the four years at Sidney was 15.15 and 14.8 for conventional and strip till, respectively. The corresponding average weights per sugarbeet were 0.69 (1.53 lbs) and 0.80 (1.76 lbs) for the same tillage treatments, respectively. For the two years at the Nesson Valley, the averages were 14.3 and 14.0 sugarbeet per 3.3 m (10 ft) of row, and 0.8 kg (1.75 lbs) and 0.81 kg (1.76 lbs) per sugarbeet for the conventional and strip till treatments, respectively.

**CONCLUSIONS AND OBSERVATIONS**

Preliminary results have shown that strip tillage will produce yields comparable to conventionally tilled sugarbeet in the Lower Yellowstone River Valley. The presence of standing small grain residue before each sugarbeet crop potentially makes strip tillage a viable way to reduce the risk of crop damage due to wind erosion in the spring. This technology should also provide substantial savings in fuel and time for local growers.

The central premise of this research is that strip tillage is not just a minimum tillage technique. It must be an integral part of an entire cultural system that minimizes equipment passes through the field while saving fuel and time. Fertilization amounts, timing and placement may have to be altered. Use of strip tillers in sugarbeet rotations after small grains will require some changes to planting and cultivation equipment and practices to handle the high residue levels. Herbicide and other pest control programs may also have to be modified to be effective in high residue conditions. Beet harvesters may require some adjustments in very heavy soils if residue and mud build up on rollers. It should be noted that the strip tillage treatment doesn’t require any more tillage than the conventional tillage following sugarbeet harvest before the succeeding barley crop.
Maintaining standing stubble is desired for wind erosion control and to trap snow in the winter. Standing stubble probably should be at least 15 cm (6 inches) or higher and needs to be sustained until the beets are sufficiently large to withstand spring wind storms.

Strip tillage is not a method that enhances weed control. Weed control programs can’t rely solely on herbicides to keep the fields clean. Control of weeds impacted by wheel traffic seems to be especially difficult for herbicides. Growers who utilize strip till must continue to cultivate using a cultivator that can handle high amounts of residue.

Almost all sugarbeet growers in the Lower Yellowstone region do most of their tillage and fertilizer applications in fall to save time during the short tillage-planting window in the spring, but can result in wind erosion problems. Fall tillage also starts the decomposition of residue earlier and the freeze-thaw cycles break down clods and “mellow” the soil, especially on heavier clay soils. Strip tillage in the fall offers the same advantages but greatly reduces the wind erosion problem.

Snow catch across a field also appears to be much more uniformly distributed under fall strip tillage compared to conventional fall tillage. Measured surface soil moisture (top 15 cm) is higher in strip tilled plots and more uniform compared to adjacent conventional till plots. This may save an irrigation to get the beets germinated. We believe that this is because there are very few or no snow drifts within the field and fewer, smaller snow drifts at the field edges. Emergence data shows that sugarbeet in a dry spring get an earlier start with strip till. In addition, even though the average soil moisture may be higher, cultural operations can potentially begin a few days earlier in the strip till because the grower does not have to wait for the relatively small areas which had the heavier snow drifts to dry out, as is often the case under conventional tillage practices.

Heavy soils must be worked at a medium moisture level in the fall to get a good seedbed under strip till. If it is worked too wet the shank merely cuts a slot, and if its too dry the clods don’t break down. Completing the strip till operation in the fall allows the strips to settle and collect moisture for better seed germination. The window of opportunity for tillage in the spring in this northern area is very short, though on a sandy soil the required conditions may be able to be met. Spring tillage would result in very little straw decomposition prior to planting which would probably make a poorer seed bed.

Strip till also requires a planter for high residue conditions such as the John Deere MaxEmergePlus with toothed-wheel row cleaners or “trash-whippers” on the front to lightly clear off loose surface residues that may blow into the tilled area over the winter to avoid any “hair pinning” of straw that might create undesirable air spaces near the sugarbeet seeds. It was determined that the planter’s seeding depth gauge wheels should be very close to the point of seed drop. Planter designs which control the seeding depth by use of a packer wheel 20 cm (8 inches) or more behind the point of seed drop may have difficulty in consistently placing the seed at the required shallow depths because of the undulations of the strip tilled seed bed.

This research used a fertilizer box mounted on the strip tiller which adds considerable weight to the machine, yet holds only a small amount of fertilizer. Practical use of dry fertilizers on a field
scale would probably require modifications to the strip tiller for a suitable air delivery system from a trailing cart. Adding the capability to apply liquid fertilizers from a trailing tank system would be fairly straightforward and should also work very well.

To date, this research has been conducted only on sprinkler irrigated sugarbeet. Strip tillage techniques should also work on furrow irrigated fields with sufficient slope (e.g., 0.3% or greater), especially if the cut straw is removed from the field following small grain harvest while leaving the standing stubble. Other irrigation parameters such as length of run and soil type would also impact the success of furrow irrigation. The retarding effect of the residue on irrigation water velocity could prove to be a benefit in fields with an excessive amount of slope where the water in the furrows tends to cut deep trenches. A project is planned for the 2009 growing season to look at strip tillage of furrow irrigated sugarbeet on grower fields.

Because of wheel compaction due to combine and truck traffic during grain harvesting, it would be desirable to strip till at an angle to the direction of travel by the combine harvester. Otherwise, tillage in the already compacted wheel rows may still have large clods and potentially result in a poor seedbed. This is not a problem under sprinkler irrigation but could be a concern under surface irrigation methods. Thus, other future research will look at ways to improve the operation of the strip tiller in breaking up heavy soils, and ways to decrease the HP requirements so that growers can utilize existing tractors as much as possible.

Fertilizer recommendations currently used for sugarbeet were developed for furrow irrigation with full tillage. It may be necessary to re-evaluate these recommendations in terms of strip tillage and sprinkler irrigation. Self-propelled sprinkler irrigation (e.g., center pivots and linear moves) also offer flexibility for split applications of nitrogen applied through the system.
