ABSTRACT

Paraffin-embedded blocks of brain of a nine months old bull calf that died of neurological signs in 1982 in Germany were restudied. Numerous schizonts and merozoites were found associated with extensive but focal necrosis and severe meningoencephalitis. Developing stages of schizonts as well as free merozoites were identified. The schizonts were primarily in perivascular areas. Ultrastructurally, schizonts were seen both in capillaries and in extravascular space. Merozoites were often concentrated in adventitial layers of capillaries. Schizonts divided by endopolyony, the nucleus became multi-lobed, and at the terminal stage nuclear lobes were incorporated into budding merozoites. Individual merozoites were seen in neurons, astrocytes, oligodendrocytes, leukocytes, and vascular endothelial cells. Occasionally merozoites were present in the nucleus of mononuclear cells. Individual merozoites were ovoid, 3–5 × 2–3 μm in size, and contained a prominent nucleus, numerous micronemes, a conoid, but no rhoptries. Schizonts and merozoites did not react to polyclonal rabbit Neospora caninum, Toxoplasma gondii, and Sarcocystis neurona antibodies but did react to Sarcocystis cruzi antibodies. Because of morphological characteristics and the type of lesions, the parasite was likely due to an unidentified Sarcocystis species, different from S. cruzi.

1. Introduction

Sarcocystis infections are common in cattle worldwide. Clinical sarcocystosis in cattle is relatively rare. Five or more species of Sarcocystis have been reported in cattle, Sarcocystis cruzi, Sarcocystis hirsuta, Sarcocystis rommeli, Sarcocystis heydorni, Sarcocystis hominis, and possibly a sixth species, Sarcocystis bovifelis (Dubey et al., 2015, 2016; Gjerde, 2016). Of these Sarcocystis species, S. cruzi is considered the most pathogenic (Dubey et al., 2016). Clinical sarcocystosis in cattle has been reported from Canada, USA, England, Norway, Ireland, and Australia (reviewed by Dubey et al., 2016). Here, we have reevaluated the case of acute sarcocystosis in a nine month old bull from Germany reported by Takla (1984); S. cruzi was considered the likely cause based on histological examination.

2. Materials and methods

In November 1986 Dr. Takla sent to one of us (JPD) two paraffin blocks from this calf for further diagnosis. After initial examination, JPD communicated to Dr. Takla in 1987 that the infection resembled Equine Protozoal Myeloencephalitis (EPM), later determined to be Sarcocystis neurona infection (Dubey et al., 2015). No further details are available because Dr. Takla passed away in 2012.

Numerous histological sections were cut from the two blocks of paraffin sent by Dr. Takla. Histological sections were examined after staining with hematoxylin and eosin.

For transmission electron microscopy (TEM), the areas with lesion (by matching with H and E sections) were deparaffinized in 1% w/v osmium tetroxide in xylene and embedded in LX-112 epoxy resin (Van den Berg Weermans and Dingemans, 1984). 60–90 nm silver gold sections were cut on a Reichert/LO Ultracut ultramicrotome with a Diatome diamond knife and mounted onto 200 mesh formvar-coated copper grids. Grids were stained with 4% uranyl acetate and 3% lead citrate and imaged at 80 kV with a Hitachi HT-7700 transmission electron microscope.

For immunohistochemical staining, deparaffinized histological sections were reacted with polyclonal rabbit antibodies to Toxoplasma gondii and Neospora caninum (Lindsay and Dubey, 1989), S. neurona (Dubey et al., 1999; Dubey and Hamir, 2000), and S. cruzi (Granstrom et al., 1990, 1991) using the previously described procedure (Dubey, 2010). Appropriate controls were used. The S. cruzi polyclonal antibodies were prepared by injecting rabbits with saline extract of bradyzoites from an experimentally infected cow; this antibody is not species specific, and even reacts with T. gondii (Granstrom et al., 1990, 1991). However, it is known to react with all Sarcocystis species that have been tested (Dubey et al., 2016).

3. Results

In both paraffin blocks there was a solitary lesion characterized by intense perivasculitis involving most capillaries in the affected area (Fig. 1A). Schizonts and intracellular and free merozoites were found only in the area with lesion (Fig. 1B, C). Only merozoites, not schizonts, were found in the perivascular infiltrate consisting of mostly mononuclear cells (Fig. 1B). Schizonts were located both in and out of blood vessels (Fig. 1C). Examples of developing stages of schizonts are shown in Fig. 2A–E. Most of these were in neural parenchyma. Fully mature merozoites were seen

G and H, immunohistochemical staining with rabbit polyclonal S. cruzi antibodies. (A) Immature schizont (arrow) with a faintly stained lobulated nucleus (arrowheads). (B) Elongated immature schizont (arrow) with more advanced lobulation of nucleus (arrowheads). (C) Immature schizont (arrow) with lobulated nucleus (arrowheads). (D) Immature schizont, presumably in a neuron. Arrow points to the host cell nucleus (arrow). (E, F) Immature schizont (arrow) with formation of merozoites. Arrowheads point to free merozoites. (G) A neuron (arrow) with 4 merozoites (arrowheads). (H) Schizont (arrow) with a rosette of merozoites.

in mononuclear cells (Fig. 2F). Individual merozoites were mostly globular, 2–3.5 μm long, and had a vesicular nucleus (Figs. 1 and 2).

Immunohistochemically, organisms stained with antibodies to S. cruzi, but not T. gondii, S. neurona and N. caninum antibodies (Fig. 2G, H).

Ultrastructurally, schizonts were seen both in capillaries and in extravascular space. Merozoites were often concentrated in adventitial layers of capillaries. Schizonts divided by endopolygeny, the nucleus became multi-lobed and at the terminal stage nuclear lobes were incorporated into budding merozoites (Fig. 3A). Individual merozoites were seen in astrocytes, oligodendrocytes, leukocytes, and vascular endothelial cells. Occasionally merozoites were present in the nucleus of mononuclear cells (Fig. 3B). Individual merozoites were ovoid, and contained a prominent nucleus, numerous micronemes, a conoid, but no rhoptries (Fig. 3C). They were 3–5 × 2–3 μm in size.

(C) A merozoite with a conoid (co), a nucleus (nu), and numerous micronemes (mn) but no rhopties.

4. Discussion

As stated earlier there are several outbreaks of clinical sarcocystosis in adult cattle (reviewed in Dubey et al., 2016). There are few cases of severe meningoencephalitis associated with a S. cruzi-like infection in cattle, simulating rabies (Table 1). Data are available from single cases where only brains were studied histologically. In the 2 cases from South Africa (Van der Lugt et al., 1994), the schizonts were much larger in size (Table 1) than reported in other cattle naturally infected with S. cruzi. There are at least three
generations of *S. cruzi* schizonts in experimentally cattle (Dubey et al., 2016). The first generation schizonts measure up to 41 μm in diameter, occur 7–26 days post inoculation (p.i.), and are found predominantly in arteries and arterioles of mesenteric and intestine. The second generation schizonts are approximately half the size of first generation, and capillaries of blood vessels in many organs. A third generation occurs in leukocytes, and detected 19–46 days p.i. (Dubey et al., 2016). The diagnosis in the case from England (Gunning et al., 2000) was based on immunohistochemical staining, and details are missing. The encephalitic case from Canada (Dubey et al., 1987) had a grossly visible area of necrosis in the cerebellum, but testing was limited to histological examination. A similar case found in a steer from Montana, USA (Dubey et al., 2016) but tissues from the animal are lost (JPD, own observations).

The case of neurological sarcocystosis reported by Takla (1984) and reevaluated here is distinct from all reports of sarcocystosis in cattle. The meningoencephalitis was most severe, lesions were focal, and *Sarcocystis* stages were confined to lesions. There were numerous free merozoites present than ever reported in cattle experimentally or naturally infected with *S. cruzi*. The parasitization was more intense in the adventitial layers of capillaries than in the endothelium. Schizonts were seen frequently extravascularly, and merozoites were seen in many types of host cells, including astrocytes, neurons, and leukocytes. Gliosis, often reported in cases of neural sarcocystosis, was not observed in the present case. Necrosis is not a predominant feature of lesions associated with *S. cruzi* infections, both natural and experimental cases.

The characteristic of lesions observed in the present case simulates *S. neurona* associated EPM in horses and other animals (Dubey et al., 2015). Dr. Takla had sent the paraffin blocks to JPD for differential diagnosis. An immunohistochemical test for EPM was not developed until 1999 (Dubey et al., 1999) and thus the decision was not made until now. There was no reactivity to antibodies to *S. neurona, N. caninum*, and *T. gondii*. The parasite reacted with *S. cruzi* antibodies, but as stated earlier this antibody is not species specific. However, staining with *S. cruzi* antibodies was very helpful in recognition of merozoites, particularly in neurons. Merozoites in sections are small (mostly 2–3 μm) and difficult to recognize. During the immunohistochemical procedure, merozoites become larger in size and thus are easily recognized. Ultrastructurally, parasites in the present case were identified in several host cells, including neural cells. Most merozoites were globular, and morphologically resembled tachyzoites of *T. gondii* in sections. Epidemiologically, *S. neurona* is not known to occur in Europe. Collectively, data suggest that another *S. cruzi*-like parasite may cause encephalitis in cattle.
