Abstract

Midday leaf CO₂ exchange rate (CER), concentration of chlorophyll (Chl) and soluble protein and activity of the primary enzymes involved in leaf photosynthesis and sucrose metabolism were determined during leaf ontogeny for sugarcane plants grown at ambient (360 μmol mol⁻¹) and double-ambient (elevated, 720 μmol mol⁻¹) CO₂. Although leaf CER of both CO₂ treatments increased and was highest at 14 days after leaf emergence (DALE), leaf CER of the elevated-CO₂ plants, however, was 20, 7 and 10% greater than that of the ambient-CO₂ plants at 7, 14 and 32 DALE, respectively. Elevated-CO₂ plants also had up to 51% lower stomatal conductance and 39% less transpiration, which resulted in 26–52% greater water-use efficiency (WUE) than ambient-CO₂ plants, during leaf growth and development. Concentrations of total Chl and soluble protein and activities of RuBP carboxylase-oxygenase (Rubisco), PEP carboxylase (PEPC), NADP-malate dehydrogenase (NADP-MDH), pyruvate P i dikinase (PPDK) and sucrose-P synthase (SPS), expressed on a leaf area basis, generally followed leaf CER patterns during leaf ontogeny. For the elevated-CO₂ plants, total Chl and soluble protein were 31 and 15% greater, and Rubisco, PPDK and NADP-MDH were up-regulated by 21, 117 and 174%, respectively, at 14 DALE, whereas PEPC and NADP-malic enzyme tended to be lower than or similar to the ambient-CO₂ plants throughout leaf development. In addition, leaf SPS activity was increased by 13 and 37% and leaf sucrose concentration was 31 and 19% higher at 7 and 14 DALE, respectively, under elevated growth CO₂. At final harvest, elevated growth [CO₂] enhanced leaf area by 31%, leaf fresh weight by 13.5%, stem fresh weight by 55.5%, total above-ground plant fresh weight by 44%, and stem juice volume by 83%. The up-regulation of the key photosynthetic and sucrose metabolism enzymes at early stages of leaf development would indicate an acclimation to elevated growth [CO₂] for the C₄ sugarcane plant. An up-regulation of the enzymes, together with a reduction in leaf stomatal conductance and transpiration and an improvement in leaf WUE and plant water status, could lead to an enhancement in leaf area, plant biomass accumulation and sucrose production for the CO₂-enriched sugarcane plants.

1. Introduction

As the present atmospheric carbon dioxide level ([CO₂]), currently at about 375 μmol mol⁻¹, limits photosynthesis and growth of many plants, rising atmospheric [CO₂] could potentially benefit agricultural crops [1,2]. In C₃ plants, the binding of atmospheric CO₂ to its primary acceptor, ribulose bisphosphate (RuBP), is catalyzed in the mesophyll cells by Rubisco, and the product of this carboxylation reaction, 3-phosphoglycerate (PGA), is converted to other carbohydrates, including sucrose and starch. In addition, Rubisco is also capable of catalyzing an oxygenase reaction in which O₂ reacts with RuBP to form PGA and phosphoglycolate. The metabolism of phosphoglycolate and subsequent release of CO₂, widely known as photospiration, have an adverse effect on the photosynthetic efficiency of C₃ plants [3]. As the balance between carboxylation and oxygenation of RuBP depends on the relative concentration
of CO₂ and O₂ at the Rubisco site, a higher atmospheric [CO₂] reduces photospiration and enhances photosynthetic CO₂ exchange rate (CER) and growth of C₃ plants [1].

C₄ plants have developed a CO₂-concentrating mechanism to overcome the limitations of low atmospheric [CO₂] and photospiration. Leaves of C₄ plants feature a Kranz architecture, having both mesophyll cells where atmospheric CO₂ is fixed by phosphoenolpyruvate carboxylase (PEPC) into C₄ acids and bundle sheath cells in which Rubisco refixes the CO₂ released from the C₄ acids [4]. Thus, the reactions that are unique to C₄ photosynthesis can be considered as an additional step to the conventional C₃ pathway. They operate to transfer CO₂ from mesophyll cells to bundle sheath cells through the intermediary of dicarboxylic acids, and consequently increase the concentration of CO₂ in the bundle sheath cells specifically for refixation via Rubisco in the C₃ photosynthetic pathway. Through this additional step, C₄ plants are able to concentrate [CO₂] at the Rubisco site to levels manifold higher than ambient [CO₂] [5,6]. Photosynthesis by C₄ plants is therefore near saturation at current atmospheric [CO₂], and a rise in atmospheric [CO₂] presumably may have little impact on C₄ photosynthesis and growth.

As a result, research of rising atmospheric [CO₂] on basic photosynthetic processes has focused mainly on C₃ species. Nevertheless, the literature does reveal a positive growth response of many C₄ plants to elevated [CO₂], although to a smaller extent than C₃ plants [7–9]. Such increases in biomass are not easily explained, because these C₄ plants often show little or no enhancement in short-term CER measurements of fully expanded mature leaves at the elevated [CO₂] used for growth, which is in contrast to the C₃ species [8–16].

Although C₄ plants represent a small proportion of the world’s plant species, their ecological and economic significance is substantial. On a global basis, about one-fifth of gross primary productivity is provided by C₄ plants [17–19]. In many tropical regions, the food source is primarily based on C₄ species, which supply grains for human consumption and forage for livestock [20]. Maize, millet, sorghum and sugarcane are the most important C₄ world crops in terms of production [20]. As the photosynthetic mechanism of a plant species is the major determinant of how it will respond to changes in [CO₂] [1], an understanding of the photosynthetic mechanisms as well as growth and development underlying the responses of economically important C₄ crops to rising atmospheric [CO₂] remains a crucial area of interest, and is essential for improvement of crop plant growth and yield efficiency in a future climate-changed world.

In the present study, sugarcane was grown at ambient and double-ambient [CO₂]. Leaf CER, concentration of chlorophyll and soluble protein and activity of the key enzymes involved in C₄ photosynthetic pathway and sucrose metabolism were determined at various periods during leaf ontogeny. Our objective was to characterize the leaf photosynthetic mechanism of sugarcane under double-ambient growth [CO₂], and to test the hypothesis that leaf photosynthesis of this C₄ crop plant is responsive to elevated growth [CO₂] at an early stage of leaf development.

2. Materials and methods

2.1. Plant material and growth conditions

Sugarcane (Saccharum officinarum L. cv. CP73-1547) was grown in Gainesville, Florida (29°38’N and 82°22’W) under field-like conditions for sunlight in paired-companion, temperature-gradient greenhouses (TGGs). The structural characteristics, specific methods and quality of CO₂ and temperature controls in the TGGs were previously described in detail [21]. These TGGs, with semi-cylindrical plastic-covered arch structures 27.4-m long, 4.3-m wide and 2.2-m high at the ridgepole, provided technology to study a wide variety of agricultural plant species grown season-long under enriched [CO₂] and a range of temperatures [21–23]. The transparent greenhouse polyethylene transmitted 90% of the solar photosynthetic photon flux density (PPFD), so that plants received direct, natural solar irradiance. Typically, for the day of 4 September 1998, a clear day, maximum PPFD measured at midday inside the greenhouse was 1805 µmol photons m⁻² s⁻¹ at plant height.

Sugarcane was first propagated vegetatively in February 1997 by placing 10-cm stalk cuttings (single-node stem cuttings containing a vegetative bud) in flats filled with a potting medium in a propagation greenhouse maintained at 30 °C. On 20 March 1997, homogeneous germinated plants were transplanted into galvanized metal containers, 1.5-m long × 0.6-m wide × 0.6-m deep, containing Arredondo fine sand, a local mineral topsoil similar to mineral soils that are used for part of Florida’s sugarcane production [24]. Eight containers were arranged in each of the two TGGs. Daytime CO₂ concentration was maintained at 360 µmol mol⁻¹ (ambient) in one TGG, and 720 µmol mol⁻¹ (double-ambient, elevated) in the other. The CO₂ values of 360 and 720 µmol mol⁻¹ were set to allow comparing the current experiment to [CO₂] treatments in experiments performed with other crop plants in the mid 1990s when the value of “ambient” [CO₂] was closer to 360 µmol mol⁻¹. Soil moisture was checked daily, and additional irrigation applied as needed to ensure adequate soil moisture for plant growth. Fertilizers containing major and microelements were applied to the soil at time of transplanting, and biweekly during the growth season, at doses recommended for commercial sugarcane production in Florida, to provide optimum nutrient supply for plant growth [24]. On 24 June 1997, main stem stalks were harvested for biomass evaluation while small young tiller stalks were let continue to grow. A second harvest of all above-ground plant material was performed in December 1997. Regrowth of new tillers began in early spring 1998, and large stem stalks were harvested on 22 June, while small young tiller stalks (<15 cm of height) were let continue to grow through the rest of the year (i.e., from July to December). On 1 September 1998, plants having main stem stalks of similar size and height were selected. The newly emerged uppermost leaves (leaf 7) of the selected plants were then tagged. Plants were about 70-day-old at this growth stage. During the months of November to April and May to October, minimum/maximum temperatures of the...
zones inside the TGGs where sugarcane plants were grown averaged 11.5 °C/24.5 °C and 20.1 °C/32.8 °C for 1997, and 11.4 °C/25.1 °C and 22.6 °C/35.1 °C for 1998, respectively.

2.2. Gas exchange measurements

CER, conductance and transpiration were determined at midday (1400–1800 μmol m⁻² s⁻¹ PPFD) on outermost sections (near leaf tips) of the attached leaf blades (leaf 7), using a LI 6200 Photosynthesis System and LI 6000-12 (1-dm³ volume) cuvette (LI-COR, Lincoln, NE), as previously reported [25]. Measurements were made at 7, 14, 32 and 48 days after leaf emergence (DALE).

2.3. Leaf sampling for biochemical analyses

Following gas exchange measurements, the outermost sections (near leaf tips) of the leaves that had been used for the photosynthetic determinations were detached from the leaf blades and immediately immersed in liquid N₂. Sampled leaves were pooled by treatment, ground to a fine powder in liquid N₂, and stored in liquid N₂ until analysis. Leaf fresh weight and area were also determined for a subset of plants at the same time of leaf sampling for biochemical analyses.

2.4. Assay of the enzymes and determination of the soluble sugars

From the liquid N₂ frozen leaf powder, activities of RuBP carboxylase-oxygenase (Rubisco), PEP carboxylase (PEPC), NADP-malate dehydrogenase (NADP-MDH), pyruvate Pi dikinase (PPDK) and NADP-malic enzyme (NADP-ME) were assayed [26]. Sucrose phosphate synthase (SPS) and concentrations of sucrose and reducing sugars (glucose and fructose) were determined as previously reported [25]. Leaf chlorophyll (Chl) and soluble protein were extracted and concentrations were measured, as described [27,28].

3. Results

Midday CER and water-use efficiency (WUE), determined at 7, 14, 32 and 48 DALE on outermost sections (near leaf tips) of the leaf blades (leaf 7) of sugarcane grown at ambient (360 μmol mol⁻¹) and double-ambient (720 μmol mol⁻¹) CO₂, are shown in Fig. 1. Leaf CER, measured at the growth [CO₂], was highest at 14 DALE for both ambient- and elevated-CO₂ plants (Fig. 1A). However, leaf CER of the elevated-CO₂ plants was 20% greater than that of the ambient-CO₂ plants at 7 DALE, and there was also a slight stimulation of 7 and 10% at 14 and 32 DALE, respectively (Fig. 1A). During leaf development, elevated-CO₂ plants, when compared with ambient-CO₂ plants, had up to 51% lower stomatal conductance and 39% lower transpiration (data not shown), and 26–52% greater in WUE (Fig. 1B).

Concentrations of total Chl (Chl a + Chl b) and soluble protein and activities of the primary C₄ photosynthetic and sucrose metabolism enzymes, determined on outermost leaf sections (near leaf tips) of the leaf blades (leaf 7) at various DALE for the ambient- and elevated-CO₂ sugarcane plants, are shown in Figs. 2–5. Changes in concentrations of total Chl and protein and activities of the enzymes, expressed on a leaf area basis, generally correlated well with leaf CER during leaf ontogeny for both CO₂ treatments. At 14 DALE, concentrations of total Chl and protein and activities of the enzymes, expressed on a leaf area basis, generally correlated well with leaf CER during leaf ontogeny for both CO₂ treatments. At 14 DALE, activities of Rubisco (Fig. 3A), PPDK (Fig. 4A) and NADP-MDH (Fig. 4B) were up-regulated by 21, 117 and 174%, respectively, for the elevated-CO₂ plants. In contrast, activity of PEPC (Fig. 3B) was 4–21% lower at all DALE, and that of NADP-ME (Fig. 5A) was 20–30% less at 7 and 14 DALE, respectively, under the CO₂-enriched growth regime.

Leaf area, leaf fresh weight, stem fresh weight, total above-ground plant fresh weight and stem juice volume, determined at final harvest for the two CO₂ treatments, were all enhanced by...
growth under elevated [CO₂] (Table 1). The enhancements for sugarcane grown under elevated [CO₂] were 31% in leaf area, 13.5% in leaf fresh weight, 55.5% in stem fresh weight, 44% in total above-ground plant fresh weight and 83% in stem juice volume, compared to companion plants grown at ambient [CO₂].

Midday activity of SPS and concentration of soluble sugars for leaves of ambient and double-ambient CO₂-grown sugarcane plants are shown in Fig. 5B and Table 2, respectively.

The growth parameters were determined at final harvest. Values are the mean ± S.E. of four plants. Means within a row followed by different letters (a and b) are significantly different at 5% level in a t-test.

Activity of SPS in the elevated-CO₂ plants was increased by 13 and 37% at 7 and 14 DALE (Fig. 5B). Compared with the ambient-CO₂ plants, leaf sucrose concentration of the elevated-CO₂ plants was 31 and 19% greater, and concentration of total soluble sugars (sucrose + reducing sugars) was increased by 26 and 15% at 7 and 14 DALE, respectively (Table 2).

Figs. 6–9 show the data of leaf CER (Fig. 1) being expressed relative to the activity of each specific enzyme (Figs. 3–5) and to the concentration of total Chl and soluble protein (Fig. 2) for each [CO₂] treatment. There was relatively good correlation (r) of CER with activity of Rubisco (Fig. 6A), PEPC (Fig. 6B) and SPS (Fig. 8B) for both [CO₂] treatments. In contrast, the relationship was weak for PPDK (Fig. 7A), NADP-MDH (Fig. 7B), NADP-ME (Fig. 8A), and total Chl and soluble protein (Fig. 9).

Leaves were sampled at midday, at 7, 14, 32 and 48 days after leaf emergence (DALE). Values are the mean ± S.E. of three determinations. Means with different letters (a–e) in the same column are significantly different at 5% level in a Duncan multiple range test.
4. Discussion

Previous studies with sugarcane and some other C₄ monocots found a response in plant biomass to elevated growth [CO₂] without the concomitant enhancement in leaf CER [11,13,29]. These short-term photosynthetic measurements, however, were carried out on fully expanded leaves. Recent studies show that leaf CER of these C₄ monocots, when measured at an early growth stage of the leaf or plant, is responsive to elevated [CO₂]. In sorghum, elevated [CO₂] enhances CER of young expanding leaves, but not mature leaves [30]. In maize, growth at elevated [CO₂] also results in greater CER early in the growth season [31]. For sugarcane in the present study, the enhancement in CER at elevated-CO₂ was more apparent during early leaf development (Fig. 1). Furthermore, there has been indication that young developing leaf tissues of some C₄ crop plants may utilize a C₃-like pathway for carbon fixation. In field-grown sorghum, Rubisco accumulates before PEPC is detected in the youngest tissues at the base of the leaf [32]. Similarly, there may be some direct entry of CO₂ into the C₃ pathway in the young leaf tissues of maize [33]. As a consequence, young expanding leaves of sorghum and maize are likely more responsive to elevated growth [CO₂] than mature leaves. In sugarcane, activities of a number of photosynthetic enzymes were up-regulated at an early growth stage of the leaf under double-ambient growth [CO₂] (Figs. 3 and 4).

A positive growth response to elevated [CO₂] has been reported for a number of C₄ plants [7–9,11,13,15,34,35]. The enhancement of C₄ biomass under elevated growth [CO₂] has been typically attributed to a reduction in stomatal aperture and conductance and a subsequent improvement in leaf water status [1,2,15,34–38]. The reduction in stomatal conductance is a common response of plants to elevated growth [CO₂] and occurs across a wide variety of both C₃ and C₄ species, although there are cases of insensitive stomatal responses [1,2,39]. Under a double-ambient growth [CO₂], the reductions in stomatal conductance range from 14 to 50% for C₄ plants, compared to about 20% for C₃ species [2,35,39]. This stomatal reduction leads to a decrease in transpiration rate and eventually an improvement in WUE for plants grown at elevated [CO₂].
In maize, mature leaves exposed to triple-ambient growth \([CO_2]\) (1100 \(\text{mol mol}^{-1}\)) had 71% lower stomatal conductance and 225% higher WUE than plants grown at 350 \(\text{mol CO}_2\text{ mol}^{-1}\) \([14]\). In the present study with sugarcane, stomatal conductance and transpiration (data not presented) were greatly reduced while leaf WUE was increased up to 52% for plants grown under double-ambient \([CO_2]\), when compared with their counterparts grown at ambient \([CO_2]\) (Fig. 1B). For \(C_4\) plants, the reductions in stomatal conductance and subsequently leaf transpiration rate can lead to an increase in leaf temperature, a conservation of soil water resource and an improvement in shoot water status \([34]\). Such effects would eventually enhance leaf CER and leaf area production rate, leading to the increases in whole plant \([CO_2]\) assimilation rate and biomass for the elevated \([CO_2]\)-grown \(C_4\) plants \([34,35]\). For sugarcane, an increase in total leaf area per plant at double-ambient growth \([CO_2]\) suggests that photosynthesis of the whole plant, and over-all carbon assimilation, would have been greater, and this may explain the over-all greater accumulation in total above-ground biomass for the elevated \([CO_2]\) plants (Table 1).

In addition to an increase in biomass accumulation, the improvement in WUE would be the greatest benefit \(C_4\) plants may have under elevated growth \([CO_2]\), especially when soil moisture is limiting \([14,38]\). As the atmospheric growth \([CO_2]\) is increased, the improvements in WUE are due to increased assimilation rate and decreased water loss, with the latter being more important under water-deficit situations \([36]\). Furthermore, as soil water becomes less available, the relative enhancement of photosynthesis and growth by elevated \([CO_2]\) tends to be greater, which can alleviate drought stress and delay its onset \([41]\).

Growth of \(C_4\) plants at elevated \([CO_2]\) can lead to an acclimation in the capacities of certain photosynthetic enzymes. In field-grown sorghum, activities of Rubisco and PEPC decrease at growth \([CO_2]\) of 200 \(\text{mol mol}^{-1}\) above the ambient level \([32]\). In maize grown at triple-ambient \([CO_2]\) and under high PPFD (2000 \(\text{mol m}^{-2} \text{s}^{-1}\)), activities of a number of \(C_3\) and \(C_4\) cycle enzymes (Rubisco, PEPC, NADP-MDH, NADP-ME and PPDK) are down-regulated \([14]\). Sorghum plants grown at double-ambient \([CO_2]\) in controlled environment chambers (12-h photoperiod at 800 \(\text{mol m}^{-2} \text{s}^{-1}\) PPFD) have a 49% reduction in leaf PEPC protein concentration, but no change in Rubisco protein content \([29]\). For sugarcane, Rubisco, PPDK and NADP-MDH activities of the elevated \([CO_2]\) plants were up-regulated at 14 DALE, while PEPC activities of both ambient- and elevated-\([CO_2]\) plants were similar during leaf development (Figs. 3 and 4). Variations in responses of the photosynthetic enzymes suggest that, among

**Fig. 8.** \(CO_2\) exchange rates (CER) vs. the activities of NADP-malic enzyme (A) and sucrose phosphate synthase (B) for outermost sections (near leaf tips) of leaf 7 of sugarcane plants grown at ambient ( ), 360 \(\text{mol CO}_2\text{ mol}^{-1}\) and double-ambient ( , 720 \(\text{mol CO}_2\text{ mol}^{-1}\) \([CO_2]\). Leaf CER and activities of the enzymes were determined at 7, 14, 32 and 48 days after leaf emergence. The solid line and broken line in each figure represent the best fitting lines for the double-ambient and ambient-\([CO_2]\) treatment, respectively, and the correlation coefficients (r values) are given in each figure.

**Fig. 9.** \(CO_2\) exchange rates (CER) vs. the concentrations of total chlorophyll (A) and soluble protein (B) for outermost sections (near leaf tips) of leaf 7 of sugarcane plants grown at ambient ( ), 360 \(\text{mol CO}_2\text{ mol}^{-1}\) and double-ambient ( , 720 \(\text{mol CO}_2\text{ mol}^{-1}\) \([CO_2]\). Leaf CER and concentrations of chlorophyll and protein were determined at 7, 14, 32 and 48 days after leaf emergence. The solid line and broken line in each figure represent the best fitting lines for the double-ambient and ambient-\([CO_2]\) treatment, respectively, and the correlation coefficients (r values) are given in each figure.
C₄ plants, species-specific differences will be encountered as a result of future increases in atmospheric [CO₂], in addition to differences in plant growth conditions and/or growth stages of the leaves.

In maize, activities of the enzymes of the sucrose and starch synthesis pathways (fructose 1,6-bisphosphatase and ADP-glucose pyrophosphorylase) are greater under triple-ambient growth [CO₂], suggesting that the increased capacity to synthesize and utilize these photosynthetic end-products could contribute to the enhancement in leaf area and plant biomass at elevated [CO₂] [14]. In sugarcane, activity of SPS and concentrations of sucrose and total soluble sugars were up-regulated at 14 DALE (Fig. 5B). This is consistent with the increases of SPS and sucrose in leaves of rice, a sucrose-accumulator C₃ plant, when exposed to long-term double-ambient growth [CO₂] [42]. The basis for increases in SPS activity and sucrose concentration in sugarcane leaves by elevated [CO₂] is still not well understood. However, since sucrose is the primary commodity being sought after in sugarcane, the implication of this for sugarcane production in the future is important, with the continued rise in atmospheric [CO₂].

Exactly how an up- or down-regulation of certain C₃ and C₄ cycle enzymes by elevated [CO₂] would regulate photosynthesis and growth of C₄ plants remains to be elucidated. However, a relatively clear picture on the role played by the individual enzymes in controlling the flux in C₄ photosynthesis has been established [43]. Through determination of the control coefficient for each enzyme of C₄ photosynthesis by measuring the CO₂ assimilation rate under saturating illumination at normal ambient [CO₂], the bulk of control in C₄ photosynthesis is shown to lie primarily with the three enzymes Rubisco, PEPC and PPDK [43]. For sugarcane, leaf CER and activities of Rubisco, PEPC and PPDK are at highest levels when measured under full sunlight [44]. Data from the present study on sugarcane leaf CER and photosynthetic enzymes, determined on a clear midday at 14 DALE, were comparable to those measured at midday on uppermost fully expanded leaves of field-grown sugarcane plants [44]. Under normal ambient [CO₂] and at full sunlight, sugarcane leaf photosynthesis may be regulated by PPDK activity, while CER may be limited by PEPC activity under low sunlight conditions [44]. For sugarcane in this study, there was a relatively good correlation of leaf photosynthetic rate with activity of Rubisco and PEPC, but not with PPDK, during the course of leaf ontogeny for both [CO₂] treatments (Figs. 6 and 7A).

Data from the present study indicate that growth of sugarcane at double-ambient [CO₂] could likely benefit through an enhancement in leaf CER, Chl and protein, and an up-regulation in the capacities of certain key photosynthetic enzymes and sucrose metabolism, during the early growth stages of the leaf. The up-regulation of these enzymes, together with the reductions in leaf stomatal conductance and transpiration and an improvement in leaf WUE under double-ambient [CO₂], may lead to an enhancement in leaf area and total plant biomass accumulation and a greater sucrose production for the CO₂-enriched sugarcane plants. The fact that large treatment differences in leaf chlorophyll and protein concentrations and photosynthetic enzyme activities, which occurred at times when differences in leaf CER were small, is still an enigma and requires further investigation. Leaf CER and associated photosynthetic activities for the sugarcane plants of both ambient- and elevated-CO₂ treatments in a future study should be determined at more frequent intervals during the first few weeks following leaf emergence. Nevertheless, even a small, but consistent, percent stimulation in leaf CER as observed at various leaf growth stages in the current experiment (Fig. 1A) could also have a contribution to the enhancement in sugarcane plant biomass accumulation under elevated growth [CO₂].
