PLANT GROWTH AND WATER USE AS AFFECTED BY ELEVATED CO_2 AND OTHER ENVIRONMENTAL VARIABLES

MISSION

To predict the effects of elevated CO_2 and climate change on the photosynthesis, growth, yield, and water use of crops under optimal and limiting levels of water and fertility.

THE FREE-AIR CO_2 ENRICHMENT (FACE) PROJECT: PROGRESS AND PLANS

B.A. Kimball, Supervisory Soil Scientist; P.J. Pinter, Jr., Research Biologist;
G.W. Wall and N.R. Adam, Plant Physiologists; R.L. LaMorte, Civil Engineer;

PROBLEM: The CO_2 concentration of the atmosphere is increasing and is expected to double sometime during this century. Climate modelers have predicted that the increase in CO_2 will cause the earth to warm and precipitation patterns to be altered. This project seeks to determine the effects of such an increase in CO_2 and any concomitant climate change on the future productivity, physiology, and water use of crops.

APPROACH: Numerous CO_2 enrichment studies in greenhouses and growth chambers have suggested that growth of most plants should increase about 30% on the average with a projected doubling of the atmospheric CO_2 concentration. However, the applicability of such work to the growth of plants outdoors under less ideal conditions has been seriously questioned. The only approach that can produce an environment today as representative as possible of future fields is the free-air CO_2 enrichment (FACE) approach. Therefore, the FACE Project was initiated; and three experiments were conducted on cotton from 1989-1991(Hendrey, 1993; Dugas and Pinter, 1994). Then, from December 1992 through May 1994, two FACE experiments were conducted on wheat at ample and limiting levels of water supply, with about 50 scientists from 25 different research organizations in eight countries participating. Another two FACE wheat experiments were conducted on wheat from December 1995 through May 1997 at ample and limiting supplies of soil nitrogen. Over 50 papers have been published (e.g., Kimball et al., 1995, 1999; Pinter et al., 1996) or are in press from these wheat experiments, and more are being prepared.

Much of the CO_2 enrichment research that has been conducted in the past has been with C3 plants and relatively little with C4 crops such as corn, sugarcane, or sorghum. The neglect of C4s was because their photosynthetic process was known to respond relatively less to elevated CO_2. However, their stomata do partially close in elevated CO_2, thereby suggesting the possibility of some water conservation. Therefore, with grants (one to USWCL and one to The University of Arizona) from the NASA/NSF/DOE/USDA/EPA (TECO III) Program, we conducted two more FACE experiments on sorghum during the summer-fall growing seasons of 1998 and 1999. Our hypothesis was that there would be only a small enhancement of growth due to the FACE treatment when the plants have ample water; but under water-stressed conditions, there would be a substantial growth enhancement resulting from the water conservation due to the partial stomatal closure.

Similar to the previous FACE experiments, measurements with the sorghum included leaf area, plant height, above-ground biomass, morphological development, canopy temperature, reflectance, chlorophyll, light-use efficiency, energy balance, evapotranspiration, soil and plant elemental analyses, soil water content, photosynthesis, stomatal conductance, video observations of roots from minirhizotron tubes, soil CO_2 and N_2O fluxes, and changes in soil C storage from soil and plant C isotopes. Some soil cores for roots also have been obtained. As before, all of the data will be assembled in a standard format for validation of plant growth models.

 Do not duplicate without prior consent.

FINDINGS: Grain samples from the final FACE wheat harvests were subjected to a battery of nutritional and bread-making quality tests, as described in more detail by Kimball et al. (2001). The water stress treatment improved quality slightly with grain protein concentrations increasing relatively about 2% and bread loaf volumes about 3%. In contrast, a low soil nitrogen supply decreased quality drastically with protein decreasing about 36% and loaf volume about 26%. At ample water, elevated CO_2 from FACE decreased quality somewhat with protein decreasing 5% (relatively) in the irrigation experiments; but in the nitrogen experiments at ample N (which had a higher level of nitrogen than in the irrigation experiments), there was no effect of CO_2 on grain quality. Loaf volume was similarly decreased 2% by elevated CO_2 in the irrigation experiments and not affected at high nitrogen in the nitrogen experiments. Elevated CO_2 tended to make the deleterious effects of low nitrogen worse, with for example, protein decreasing 33% at ambient CO_2 and 39% under FACE. Loaf volume similarly decreased 22% at ambient and 29% under FACE.

As reported in more detail by Ottman et al. (2001), stover yield from the FACE sorghum experiments responded slightly to CO_2; and over the two seasons and over the Wet (ample) and Dry (water stress) irrigation treatments, it averaged 848 g m^{-2} for the control and 928 g m^{-2} for FACE (+9 %). In the Dry plots, grain yield increased due to elevated CO_2 from 472 to 553 g m^{-2} (+17%) in 1998 and 106 to 142 g m^{-2} (+34%) in 1999. In the Wet plots, however, grain yield was not influenced by elevated CO_2 in 1998, but decreased due to elevated CO_2 from 476 to 424 g m^{-2} in 1999 (-12%). Sorghum phenological development was not affected in a consistent manner by elevated CO_2. Elevated CO_2 had the general effect of slowing growth in the Dry plots and accelerating growth in the Wet plots during the vegetative stages, but causing the reverse after anthesis during grain fill. Leaf senescence was accelerated in the Wet plots and may have been partially responsible for the lack of grain yield response to CO_2 with ample water. In water-stressed sorghum, stomatal closure due to elevated CO_2 had a negative effect on growth early and only later in the growth cycle were the positive benefits of soil water conservation realized.

INTERPRETATION: The FACE wheat grain quality data suggest that future elevated CO_2 concentrations will exacerbate the deleterious effects of low soil nitrogen on grain quality; but with ample fertilizer nitrogen, the effects will be minor.

The FACE sorghum data suggest that under conditions with ample water, the higher future atmospheric CO_2 concentrations may cause a slight decrease in sorghum yield due to an accelerated grain-filling period. On the other hand, under water-stress conditions, which are typical of much of the rain-fed areas where sorghum is grown in the U.S. and in Africa and other developing countries, the future higher levels of CO_2 are likely to increase productivity by 15% or more.

FUTURE PLANS: Analyses and reporting of the results from the FACE wheat and especially from the sorghum experiments will continue. Consensus from the participating investigators is that a FACE alfalfa experiment should be conducted next. Specific reasons to focus attention on alfalfa as an experimental crop are as follows: (1) Being deep-rooted, alfalfa could potentially sequester carbon at greater depths below the plow layer where the carbon may be stored for much longer periods than is possible with many other plants. (2) Because alfalfa is a perennial crop that grows the year around with about 8 cuttings per year in our climate, growth observations can be obtained over a very wide range of temperatures and, therefore, the interaction between elevated CO_2 and temperature can be studied. (3) Because alfalfa is a legume, the effects of elevated CO_2 on nitrogen fixation can be

examined as can the importance of nitrogen for C sequestration. (4) Alfalfa is an important crop in the U.S. (4th in acreage behind wheat, corn, and soybeans), and it grows well in Arizona. Unfortunately, funding is not currently available to conduct such an experiment; a proposal has been submitted NASA to obtain such funding.

FREE-AIR CARBON DIOXIDE ENRICHMENT (FACE): EFFECTS ON SORGHUM EVAPOTRANSPIRATION IN WELL-WATERED AND WATER-STRESSED IRRIGATION TREATMENTS

M. M. Conley, Physical Science Technician; B. A. Kimball, Supervisory Soil Scientist;
P. J. Pinter, Jr., Research Biologist; D. J. Hunsaker, Agricultural Engineer;
G. W. Wall and N. R. Adam, Plant Physiologists; and R. L. LaMorte, Civil Engineer

PROBLEM: The 1996 Intergovernmental Panel on Climate Change (IPCC) projects that, if 1994 CO_2 emission levels are sustained, the global atmospheric CO_2 concentration will reach 500 μmol mol^{-1} by the year 2100. Such an increase in CO_2 concentration is likely to decrease plant evapotranspiration (ET) and increase plant water-use efficiency (WUE).

APPROACH: Eight 490 m^2 rings were subjected to two levels of CO_2 (F = FACE, C = Control) and two levels of soil water supply (W = Wet, D = Dry) as described in detail by Ottman et. al. (2001).

Soil water content measurements: Volumetric soil moisture content was determined with the neutron probe (Hydroprobe Model 503 DR, Campbell Pacific Co., Martinez CA). The calibration equation used was: $\theta = 0.015 + 0.156$ * (count / standard count) where θ = volumetric soil water content (θ: m^3 H_2O / m^3 soil). Measurements were taken at 0.3 m intervals to either 1.8 m or 3.0 m depths during the 1998 and 1999 seasons, respectively.

Active root depth was determined by estimating the expected water extraction front from 0-1.76 m (Robertson et al., 1993). ET was calculated only for the zone of soil containing active roots. ET was calculated during drying periods by using a soil water balance equation (Jensen et al., 1990).

FINDINGS: Temporal changes in soil water content: During 1998, volumetric soil water content measurements (Fig. 1a) showed two distinct dry-down periods for the Dry plots - the first from day of year (DOY) 228-254 and the second from DOY 275-330. We observed three dry-down periods in the Dry treatment during 1999: DOY 198-218, DOY 228-258, and DOY 268-290. During 1998, periods of plant stress in Dry treatments, as inferred from a 30% drop in soil moisture below field capacity, occurred during DOY 247-253 and DOY 290-325, whereas they occurred from DOY 202-218, DOY 244-258, and after DOY 280 until maturity during 1999 (Fig. 1b).

Evapotranspiration: During the first year (1998), major differences in cumulative ET between Wet and Dry treatments were apparent by DOY 273 (Fig. 2a). Aside from a divergence during DOY 260-290, when plants were undergoing reproductive growth, FD and CD treatments showed similar patterns in cumulative ET. However, significant differences between CO_2 treatments were evident in Wet plots beginning on DOY 260. FW plots evapotranspired 60 mm (±117 mm) or 11% less than CW over the entire growing season. Seasonal ET in the Dry treatment revealed FD evapotranspired 1 mm (±22 mm) or 0% less than CD. During 1999, differences in cumulative ET between Wet and Dry treatments began at DOY 220, becoming more pronounced after DOY 240 (Figure 2b). ET differences between CO_2 levels were evident within the Wet irrigation treatment from DOY 230 through the end of the season when FW had consumed 58 mm (±34 mm) or 9% less water than CW plants. Seasonal ET in the Dry treatment revealed FD evapotranspired 25 mm (±14 mm) or 6% less than CD.

Figure 1: Mean volumetric soil water contents (from 0.0 to 1.8 m depth) in the Control-Dry (CD), FACE-Dry (FD), Control-Wet (CW), and FACE-Wet (FW) plots for the 1998 (1) and 1999 (b) sorghum growing seasons. Bars denote standard errors. Each mean is the average of four replicates. A indicates when only Wet plots were irrigated. B indicates when both Wet and Dry plots were irrigated. NS, *, **, *** = Not significant at P > 0.25 and significant at P < 0.25, 0.15, 0.05, respectively.

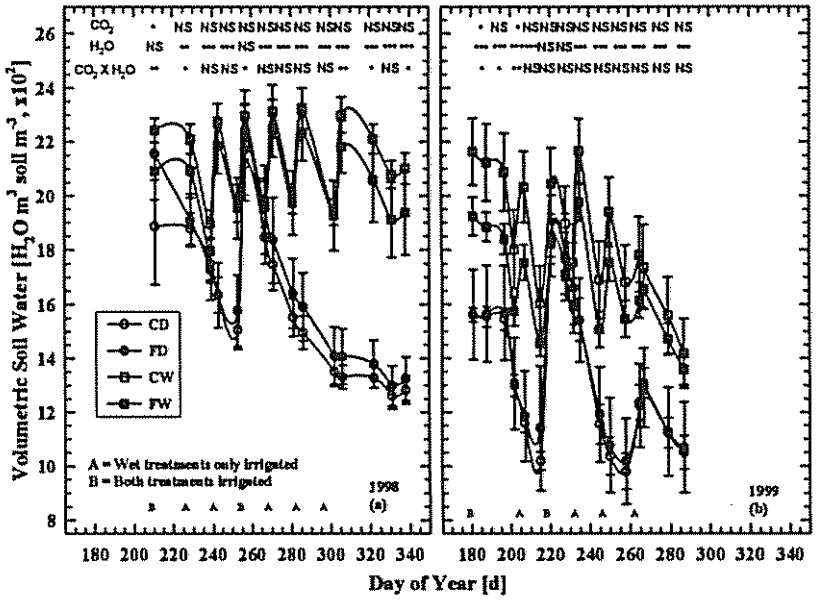

Figure 2: Mean cumulative evapotranspiration (ET) for the Control-Dry (CD), FACE-Dry (FD), Control-Wet (CW), and FACE0-Wet (FW) plots in 1998 (a) and 1999 (b) sorghum growing seasons. Bars denote standard errors. Each mean is the average of four replications. The dotted line represents modeled ET from the Arizona Meteorological Network AZMET (Brown, 1987) adjusted for sorghum. NS, *, **, *** = Not significant at P > 0.25 and significant at P < 0.25, 0.15, 0.05, respectively.

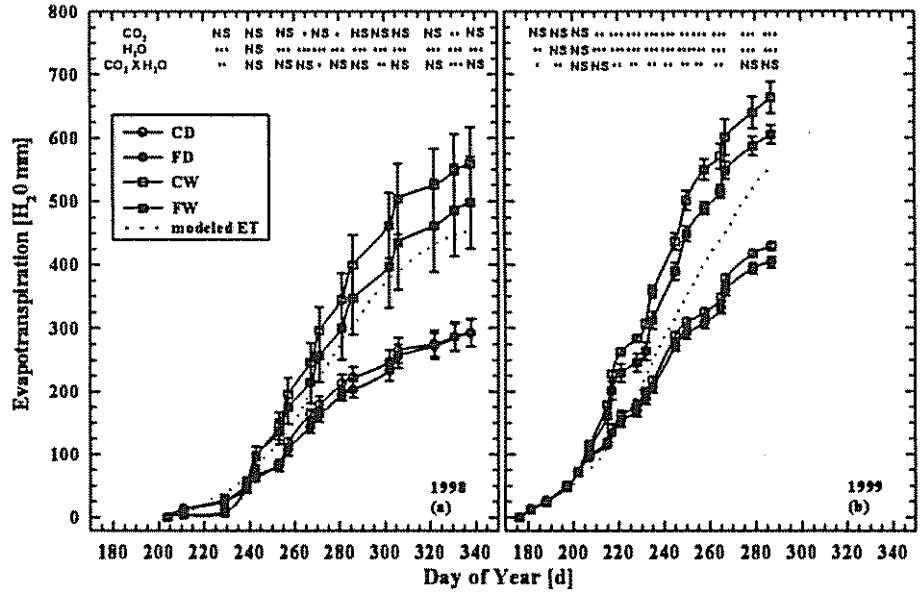

Water-use Efficiency: Grain yield and total above-ground biomass were measured in 1998 and 1999 by Ottman *et al.* (2001). Water-use efficiency based on grain yield (WUE-G) was calculated as the ratio of grain yield per square meter, per mm of ET (Table 1). Water-use efficiency based on total biomass (WUE-B) was calculated as the ratio of biomass per square meter, per mm of ET (Table 2). Based on the two year average, the WUE-G for FD was 0.18 (±0.21) $g/m^2/mm$ or 19% greater than CD, and FW was 0.08 (±0.1) $g/m^2/mm$ or 9% greater than CW; WUE-B for FD was 0.5 (±0.49) $g/m^2/mm$ or 17% greater than CD, and FW was 0.42 (±0.33) $g/m^2/mm$ or 16% greater than FW. This suggests an increasing WUE due to CO_2 enrichment with increasing water stress. Additionally, CO_2 enrichment caused a larger relative increase in grain yield than in total biomass. Such yield increases in grain and total biomass are likely without additional use of water resources at higher than ambient CO_2 concentrations.

Table 1: Sorghum grain yield (Ottman et al. 2001), ET, WUE-G, and the percent difference in WUE-G based on yield and due to FACE enrichment.

Increased plant water stress due to increased water demand coupled with decreased total applied water can explain the large decrease in yield, biomass, and WUE in 1999 relative to 1998.

Elevated CO_2 increased WUE-G by 0.13 (±0.16) g/m^2/mm or 14% and WUE-B by 0.46 (±0.41) g/m^2/mm or 16%. CO_2 enrichment caused partial stomatal closure, reduced stomatal conductance, and decreased transpiration per unit of leaf area in both Wet and Dry plots (Wall et al., 2001). Sorghum did not exhibit an increased leaf area in Wet plots (Ottman et al., 2001) so there was conservation of water (Figure 2a,b). In the Dry plots, CO_2-enriched plants had reduced stomatal conductance (Wall et al., 2001), which conserved water and enabled them to grow further into a drying cycle. Cumulative evapotranspiration of FD and CD plants were similar (Figure 2a,b). FD plants grew more (Ottman et al., 2001) and had a greater WUE than CD plants. Therefore, we accept the hypothesis that elevated CO_2 will cause sorghum to decrease ET under wet conditions and to increase WUE under both wet and dry conditions.

INTERPERTATION: Our data show that future water requirements for irrigated sorghum should decrease slightly, provided global warming is minimal. Under rain-fed conditions, where sorghum is more likely to experience water stress, elevated CO_2 will likely cause a productivity increase in total biomass and specifically grain yield. Moreover, under ample-water and, especially, water-limited conditions, increases in CO_2 are likely to cause WUE to increase substantially.

FUTURE PLANS: We plan to run ANOVA analysis of theta by depth using SAS. We will make ET and WUE measurements on alfalfa (Kimball et al, this volume).

COOPERATORS: See Kimball et al. (this volume).

ENERGY BALANCE AND EVAPOTRANSPIRATION OF SORGHUM: EFFECTS OF FREE-AIR CO_2 ENRICHMENT (FACE) AND SOIL WATER SUPPLY

B.A. Kimball, Soil Scientist; J.M. Triggs and T.J. Brooks, Research Technicians; M.M Conley, Physical Science Technician; R.L. LaMorte, Civil Engineer; C. O'Brien, Research Assistant; P.J. Pinter, Jr., Research Biologist; G.W. Wall and N.R. Adam, Plant Physiologists; T.R. Clarke, Physical Scientist; and R. Rokey, Biological Technician

PROBLEM: The CO_2 concentration of the atmosphere is increasing and is expected to double sometime during this century. Climate modelers have predicted that the increase in CO_2 will cause the earth to warm and precipitation patterns to be altered. Such increases in CO_2 and possible climate change could affect the hydrologic cycle and future water resources. One component of the hydrologic cycle that could be affected is evapotranspiration (ET), which could be altered because of the direct effects of CO_2 on stomatal conductance and on plant growth. Therefore, one important objective of the Free-Air CO_2 Enrichment (FACE) Project (Kimball et al. this volume) is to evaluate the effects of elevated CO_2 on the ET of sorghum and other crops.

APPROACH: We conducted two FACE experiments on sorghum from mid-July to mid-December 1998 and again from mid-June to the end of October 1999 (Kimball et al., this volume).

Briefly, the FACE apparatus consists of the following: Four toroidal plenum rings of 25 m diameter constructed from 12" irrigation pipe were placed in a sorghum field at Maricopa, Arizona, shortly after planting. The rings had 2.5-m-high vertical pipes with individual valves spaced every 2 m around the periphery. Air enriched with CO_2 was blown into the rings, and it exited through holes at various elevations in the vertical pipes. Wind direction and speed were measured adjacent to each FACE ring, and CO_2 concentration was measured at the center of each. A computer control system used wind direction information to turn on only those vertical pipes upwind of the plots so that the CO_2-enriched air flowed across the plots no matter which way the wind blew. The system used the wind speed and CO_2 concentration information to adjust the CO_2 flow rates to maintain desired CO_2 concentrations at the centers of the rings. The FACE CO_2 concentration was elevated by 200 ppm CO_2 above ambient (about 360 ppm in daytime) 24 hr/day all season long. Four matching Control rings with blowers to provide air flow but no added CO_2 were also installed in the field. Some additional measurements were made in mid-field areas between the FACE and Control plots where neither CO_2 nor air flow were altered.

In addition to the CO_2 treatments, varying soil water supply was also a factor. Using a split-plot design, the main circular CO_2 plots were divided into semicircular halves, with each half receiving an ample irrigation regime (Wet) or else receiving a water-stress treatment (Dry). Using flood irrigation, the Wet plots were irrigated on roughly a two-week schedule, whereas the Dry plots were irrigated only twice (shortly after planting and at mid-season).

The determination of the effects of elevated CO_2 on ET by traditional chambers is fraught with uncertainty because the chamber walls that constrain the CO_2 also affect the wind flow and the exchange of water vapor. Therefore, as done previously in the FACE cotton and wheat experiments (Kimball et al., 1994, 1995, 1999), a residual energy balance approach was adopted whereby ET was calculated as the difference between net radiation, R_n, soil surface heat flux, G_0, and sensible heat flux, H:

 Do not duplicate without prior consent.

$$\lambda ET = R_n - G_0 - H$$

R_n was measured with net radiometers and G_0 with soil heat flux plates. H was determined by measuring the temperature difference between the crop surface and the air and dividing the temperature difference by an aerodynamic resistance calculated from a measurement of wind speed. Air temperatures were measured with aspirated psychrometers, and crop surface temperatures were measured with infrared thermometers (IRTs) mounted above each plot. Fifteen-minute averages were recorded on a datalogging system. The net radiometers and IRTs were switched weekly between the FACE and Control plots.

The instruments were calibrated carefully before the start of the experiments and again between the experiments in early 1999. During 2000, final calibrations were performed, including some comparisons among instruments from various manufacturers to use as reference standards. Analysis of the data from the standards comparisons is completed, and now analysis of the field data themselves is progressing.

FINDINGS: The micrometeorological data have not yet been analyzed, and so no report of the effects of the FACE treatment on the energy-balance-determined **ET** of sorghum can be made. In the prior FACE cotton experiment, the cotton had a large growth response (40% increase) to the elevated CO_2, but no effect on **ET** was detectable (Kimball et al., 1994). In contrast, with wheat which had a modest growth response (about 20%), the FACE treatment decreased **ET** by an average 6.7% (± 1.2%) for the four seasons under Wet, high-nitrogen conditions. Under low nitrogen and ample nitrogen, the reduction in **ET** was 19.5% (Kimball et al., 1999).

The sorghum growth response to elevated CO_2 amounted to about +9% averaged over two seasons and over the Wet and Dry irrigation treatments (Ottman et al., 2001; Kimball et al., this volume); so, based on the growth and energy balance comparisons from the past cotton and wheat experiments, we hypothesize that there was a slight reduction in sorghum **ET**. However, another basis for this hypothesis is that such a slight reduction was deduced from an analysis of the soil water balance by Conley et al. (this volume). They found that **ET** was reduced about 11% in Wet plots due to the FACE treatment, as averaged over the two growing seasons; whereas in the Dry plots, it was increased an average 3%.

INTERPRETATION: It appears from the prior FACE cotton experiments that cotton irrigation requirements will not change, whereas for wheat they may be somewhat lower in the future high-CO_2 world (provided that any global warming is small). We hypothesize that the sorghum irrigation requirements will also be reduced slightly, but we can make no definitive statement about them yet.

FUTURE PLANS: We plan to complete the analysis of the micrometeorological data from the two FACE sorghum experiments and write the corresponding manuscript.

RELATIONSHIPS OF A-CI PARAMETERS AND ENZYME ACTIVITIES IN SORGHUM EXPOSED TO FREE-AIR CO_2 ENRICHMENT (FACE)

N. R. Adam and G.W. Wall, Plant Physiologists; B.A. Kimball, Supervisory Soil Scientist; P.J. Pinter Jr., Research Biologist; and R.L. LaMorte, Civil Engineer

BACKGROUND: With the expected doubling of atmospheric levels of CO_2 sometime in the 21st century, it is important to understand how this change will affect our way of life and, more generally, how it will affect plant life. The Free Atmospheric CO_2 Enrichment (FACE) facility at The University of Arizona Maricopa Agricultural Center is helping to determine how plants respond and acclimate to long-term exposure to elevated levels of CO_2 in the field.

Plants acclimate to changes in CO_2 concentration through changes in the amounts and activities of enzymes required to reestablish a balance within the photosynthetic apparatus. An earlier report (Adam *et al.*, 1997) presented data from a gas-exchange technique in which photosynthesis (A) was measured at a range of intracellular CO_2 concentrations (Ci), which provided information on changes within the photosynthetic apparatus of spring wheat, a so-called C_3 plant. Adam *et al.* (1998) showed that in spring wheat, the slope of the A-Ci relationship at those low values of Ci could be used to assess the changes in the activity and content of Rubisco due to growth in increased levels of CO_2. The work with spring wheat also indicated that, in order to fully assess the response of crop plants to elevated CO_2, various growth stages and canopy, a profile must be measured.

Similar experiments were conducted in 1998 and 1999 on sorghum, a warm-season crop with a different carbon-trapping mechanism, therefore, called a C_4 plant. The carbon-trapping enzyme of sorghum is PEPCase which, unlike Rubisco, fixes only carbon. The product of the reaction catalyzed by PEPCase is then shuttled to Rubisco and into the Calvin cycle. The relationships between the A-Ci curves and metabolic processes of C_4 plants are not fully understood. One objective of these experiments was to investigate the effect of growth in elevated CO_2 on these C_4 pathway enzymes in sorghum, as well as on the A-Ci relationships.

APPROACH: *Sorghum bicolor* (L.) Moench (cv. Dekalb 54) was planted in an open field at The University of Arizona Maricopa Agricultural Research Center, located 50 km south of Phoenix, Arizona (33.1 °N, 112.0 °W). Sorghum was planted on July 13 and 14, 1998, and again on June 14 and 15, 1999 (Kimball et al., 1999). Fifty percent emergence occurred July 30, 1998, and July 1, 1999. Following sowing, FACE apparatus was erected on site to enrich the CO_2 concentration of the ambient air (ca. 370 μmol mol^{-1} during daytime) by 200 μmol mol^{-1} above ambient. Water was applied as a split plot factor using flood irrigation such that "Wet" plots received ample water while "Dry" plots received only two irrigations and were severely stressed. All plots received 278.7 kg ha^{-1} N.

For the first sampling date (the 4th and 5th leaf stages in 1998 and the 2nd through 5th leaf stages in 1999), gas exchange analyses were conducted on the uppermost fully-expanded leaf (referred to as the top leaf) and on the top minus one leaf. Thereafter, measurements were made on the top leaf and the top minus two leaf. Photosynthesis (A) rates were measured over a range of intercellular CO_2 (Ci) levels, generating an A-Ci curve. At the end of each curve, the leaf was frozen as quickly as possible with a liquid nitrogen-cooled clamp and stored in liquid nitrogen. Activity of Rubisco,

 Do not duplicate without prior consent.

PEPCase and PpdK were assayed from leaves collected from both years. Parameters estimated from the A-Ci curves were the initial slope, the bend (or inflection) of the curve, and the asymptote.

FINDINGS: The A-Ci curves in the early growth stages (i.e., 2nd and 3rd leaf stages) were found to resemble a C_3-type curve. However, as the plants reached the 4th and 5th leaf stage, the curves were more similar to a typical C_4 curve (Fig. 1a), in that the initial slope of the curve is steeper. We also found that the curves became more C_3-like as water stress became more severe (Fig. 1b) and became more C_4-like after irrigation (Fig. 1c). Step-wise regression showed that the enzyme activities measured explained 50% or less of the variation seen in the parameters of the A-Ci curves (Table 1) and that the initial activity of Rubisco was the enzyme parameter most closely related to all three portions of the curve.

INTERPRETATION: The initial activity of Rubisco was not expected to be related to all three portions of the curve. In addition, PEPCase was expected to be related to the initial slope of the curve. It is likely that factors other than enzyme activity are more important in determining the shape of the A-Ci curve and that the initial activity of Rubisco is responding to the factors that determine the shape of the curve. Although leaf samples from some of the measurement dates remain to be assayed, it appears that factors other than enzyme activity or concentration (for example, water status of the plant) will be more important in determining the response of sorghum plants to future climatic changes.

FUTURE PLANS: Biochemical assays will be conducted on both the remaining samples to determine whether these relationships change. In addition, further analysis of the effects of growth in CO_2 enrichment and water stress on these relationships will be conducted.

COOPERATORS: See Kimball et al., this volume. However, we especially wish to acknowledge the collaborative efforts of Andrew Webber of Arizona State University for helpful advice and the use of his laboratory. We also thank Jonathan Triggs and Jose Olivieri for technical assistance.

Effects of Elevated CO_2 and Water and Nitrogen Stress on Phenology of Spring Wheat

P. J. Pinter, Jr., Research Biologist; B. A. Kimball, Supervisory Soil Scientist; G. W. Wall, Plant Physiologist; R. L. LaMorte, Civil Engineer; F. J. Adamsen, Soil Scientist; D. J. Hunsaker, Agricultural Engineer; and T.J. Brooks, Research Technician

PROBLEM: Terrestrial ecosystems will probably experience a significant increase in atmospheric CO_2 during this century. The potential effect of this change on important food and fiber crops has been the subject of extensive research by U.S. Water Conservation Laboratory (USWCL) scientists for more than a decade. In our research, we have been using Free-air Carbon dioxide Enrichment (FACE) to expose plants to supra-ambient levels of CO_2 because FACE minimizes the microenvironmental and climatic artifacts that are often associated with studies using open-top chambers or greenhouses. Various performance measurements have shown that the FACE facility provides very good temporal and spatial control of CO_2 concentrations and is a cost-effective means for large scale fumigation experiments.

Our strategies for CO_2 exposure and the sophistication of ambient CO_2 control plots have evolved over the years as FACE has been applied to different crops. Modifications have also been made as experimental objectives have changed and as more was learned about system behavior under different environmental conditions (Pinter *et al.*, 2000). When the focus of our FACE project shifted from cotton to spring wheat, a decision was made to enrich the plots on a 24h day^{-1} basis. Because of the extra costs involved, the control plots used during the first two years experimentation in wheat (1992-93 and 1993-94) had dummy plastic manifolds and standpipes but were not equipped with blowers. However, with the new 24h day^{-1} protocol, we began to suspect that the blowers used to introduce CO_2-rich air into the elevated CO_2 arrays was causing some slight additional microturbulence in the boundary layer above the canopy, especially during calm nights. Although subtle and difficult to measure with the mechanical cup anemometers in our micrometeorological instrumentation, the additional disturbance resulted in a slight increase in air and radiant canopy temperatures in the blower-equipped plots at night. We also suspected and later confirmed that the slightly higher temperatures were associated with differences in plant phenology and end-of-season senescence rates.

Wheat FACE experiments were carried out for another two years, through the 1995-96 and 1996-97 growing seasons. For these experiments, however, blowers were installed in the experimental control plots (hereafter called blower plots), and we did not observe differences between FACE and blower plots in nighttime air temperatures, canopy temperatures, plant phenology, or senescence. The objectives of this report are to clarify that CO_2 did not have a direct effect on wheat developmental rates and to discuss the overall stimulatory effect of CO_2 on final grain harvest from all four years of the experiment.

APPROACH: FACE field experiments were conducted at The University of Arizona Maricopa Agricultural Center (MAC). Spring wheat (*Triticum aestivum*, L. cv Yecora Rojo) was sown in mid-December, emerged on or about January 1, and was harvested near the end of May in each year. Irrigation was accomplished via subsurface drip tubing. A split, strip plot design incorporated two levels of CO_2 as the main treatment effect during all four years with levels consisting of ambient Control (~360 $\mu mol\ mol^{-1}$) and elevated FACE (a nominal 550 $\mu mol\ mol^{-1}$)

 Do not duplicate without prior consent.

concentrations. The secondary treatment variable during the first two years (CO_2 by water experiments, 1992-93 and 1993-94) included two levels of irrigation: Wet (100% of consumptive requirements) or Dry (50% of Wet). The secondary treatment variable in the final two years (CO_2 by N experiments, 1995-96 and 1996-97) was applied nitrogen: High (~388 kg ha^{-1} yr^{-1}) and Low (~77 kg ha^{-1} yr^{-1}). More complete details on experimental design and treatment conditions may be found in Kimball *et al.* (1999), Hunsaker *et al.* (2000), and Pinter *et al.* (2000).

Plants were sampled at 7-10 day intervals using similar techniques all four years. Main stems were assigned growth stages according to the Zadoks scale of plant development. Dates when plants reached the midpoint of eight principal growth stages (tillering, stem elongation, booting, heading, anthesis, milk development, soft dough, and ripening) were computed via linear interpolation and then averaged for all replicates within a treatment combination. We computed the difference in chronological time required to reach a specific growth stage between plots with and without blowers (i.e., control minus FACE for 1992-93 and 1993-94) and also between plots having blowers but exposed to either ambient or elevated CO_2 levels (i.e., blower minus FACE for 1995-96 and 1996-97). Paired "t" tests were used to determine the statistical significance of these differences in phenology.

FINDINGS: Qualitative observations of plants growing in the field revealed relatively large differences in phenology (at heading, anthesis, and maturity) between control and FACE plots in the CO_2 by water experiments that were not evident when comparing blower and FACE plots in CO_2 by N experiments. Zadoks growth stage data from the periodic plant samples confirmed these observations. Development in plots with blowers was accelerated by 2 to 5 days compared to plots without blowers. The CO_2 treatment by itself appeared to have minimal effect on developmental rates. Paired "t" test comparisons showed the average differences in phenology between elevated CO_2 FACE plots and the ambient CO_2 control (without blowers) during 1992-93 and 1993-94 were relatively large and highly significant in both the Wet and Dry irrigation treatments (Table 1). The chronological differences in developmental rates between FACE and blower treatments during 1995-96 and 1996-97 were less than 0.5 days and only under deficit nitrogen conditions were the differences between CO_2 treatments statistically significant.

Table 1. Mean differences in the time required to reach each of 8 primary growth stages (tillering → ripening) between different Blower and CO_2 configurations used during the FACE Wheat experiments at Maricopa, AZ.

[†] Treatment abbreviations: C, Control; B, Blower; F, FACE; W, Wet irrigation; D, Dry irrigation; H, High nitrogen; L, Low nitrogen.[‡] Refers to the total number of paired observations. Only 3 replicates were available for *t* test comparisons during most of the 1996-97 experiment.

INTERPRETATION: One of the unique findings of the 1992-93 and 1993-94 FACE experiments was the apparent accelerating effect of elevated CO_2 on plant development and rates of canopy senescence (as reported by Pinter et al., 1996; and photograph in Kimball et al., 1995). A reexamination of those data in light of the slight differences in temperature we now know to exist between the treatments and the new phenology results from the CO_2 by N experiments have led us to conclude that the blower effect was sufficient to explain most of the apparent developmental acceleration. The subtle, blower-related rise in nighttime temperatures had cumulative effects on long-term developmental processes of the wheat plant. We now believe that elevated CO_2 *per se* had very little effect on the rates of plant development in well-watered and amply-fertilized spring wheat.

What effect might the blowers have had on CO_2 enhancement of final grain yields? We had originally reported only a 10% increase in yield for wheat exposed to CO_2 at 550 μmol mol^{-1} and supplied with adequate water and nutrients, suggesting that plants in the Control treatment had additional opportunity to "catch up" with the sink-limited FACE plants (Pinter et al., 1996; and Kimball et al., 1995). We now believe that this 10% figure was probably an underestimate of the true CO_2 effect that might have been observed during the first 2 seasons had the controls been properly equipped with blowers and the grain filling duration of both CO_2 treatments been similar. In fact, during the 1995-96 and 1996-97 experiments, grain yields for adequately fertilized and well-watered wheat showed a 15% increase associated with a nominal +200 μmol mol^{-1} CO_2 elevation. This translates into a CO_2 enhancement (β) factor of ~28% for a doubling of atmospheric CO_2 concentrations, an increase which compares favorably with the 33% average for agricultural crops reported by Kimball (1983).

There is little argument that the FACE technique approaches natural conditions more closely than open-top chambers or other means of exposing plants to elevated CO_2. Important advantages include an unmodified light environment, unrestricted rooting volume, and large experimental areas. Despite our results showing that the blowers cause a slight modification of crop microclimate, the advantages of FACE over open-top chambers and greenhouses still outweigh disadvantages by a considerable margin. However, these findings emphasize the importance of equipping control plots in FACE facilities with blowers and point out a disadvantage to nighttime CO_2 enrichment in our region.

FUTURE PLANS: A manuscript dealing with interactive effects of elevated CO_2 and water or nitrogen stress on wheat plant growth and final yields is in preparation.

LONG-TERM CO_2 ENRICHMENT OF SOUR ORANGE TREES: EFFECTS ON PRODUCTIVITY AND CARBON SEQUESTRATION

S.B. Idso, Research Physicist; and B.A. Kimball, Supervisory Soil Scientist

PROBLEM: Many people believe the ongoing rise in the air's CO_2 content is the greatest problem ever to be faced by humanity based on the assumption that it could lead to catastrophic global warming via intensification of the planet's natural greenhouse effect. However, elevated concentrations of atmospheric CO_2 also provide many benefits, some of which tend to ameliorate the global warming problem. Earth's trees, for example, account for approximately two-thirds of the planet's photosynthesis, by which means they remove prodigious amounts of CO_2 from the air and sequester its carbon in their tissues and the soil beneath them, thereby slowing its rate of rise in the atmosphere. Consequently, we seek to determine the direct effects of atmospheric CO_2 enrichment on all aspects of the growth and development of trees concentrating on the long-term aspects of the phenomenon; for until someone conducts an experiment measured in *decades*, we will never know the ultimate impact of the ongoing rise in the air's CO_2 content on the planet's most powerful contemporary carbon sink.

APPROACH: In July 1987, eight 30-cm-tall sour orange tree (*Citrus aurantium* L.) seedlings were planted directly into the ground at Phoenix, Arizona. Four identically-vented, open-top, clear-plastic-wall chambers were then constructed around the young trees which were grouped in pairs. CO_2 enrichment – to 300 ppmv (parts per million by volume) above ambient – was begun in November 1987 in two of these chambers and, other than for brief maintenance and construction periods, has continued unabated since that time. Except for this differential CO_2 enrichment of the chamber air, all of the trees have been treated identically, being irrigated and fertilized as deemed appropriate for normal growth (Idso and Kimball, 1997).

As in all prior years, we continue to measure the circumferences of the trunks of the trees at the midpoint of each month; and from these data, we calculate monthly values of total trunk plus branch volume on the basis of relationships developed specifically for our trees (Idso and Kimball, 1992). Then, from wood density (dry mass per fresh volume) measurements we have made over the past several years, we calculate monthly values of the total dry weight of the trunk and branch tissue of each tree. Results for December, January, February and March – the winter period of minimal trunk expansion – are then averaged to give a mean value for the year, from which the preceding year's mean value is subtracted to yield the current year's production of trunk and branch biomass.

We likewise continue our yearly fruit measurements, counting the number of fruit to reach maturity on each tree, weighing the fruit, and calculating the total dry weight of fruit produced in each of the CO_2 treatments from previous determinations of fruit percent dry weight. Also from previously derived relationships (Idso and Kimball, 1992), we evaluate the number of new leaves produced each year from our trunk circumference measurements; and from bimonthly assessments of leaf dry weight similar to those of Idso et al. (1993), we calculate the total dry weight of leaves produced each year. These results, added to the trunk and branch dry weights and fruit dry weights, then give us the total aboveground dry weight production per year for all of the trees in the two CO_2 treatments.

 Do not duplicate without prior consent.

When viewed in their entirety, the results continue to be encouraging. They indicate that the trees of both CO_2 treatments may be close to achieving a stage of maturity characterized by a near-steady-state of yearly aboveground biomass production (Fig. 1). For the last five years of the experiment, for example, the values of total aboveground biomass in the CO_2-enriched trees were 107, 90, 95, 116, and 89 kg/tree; while those for the ambient-treatment trees were 62, 51, 57, 61, and 55 kg/tree, producing a five-year-mean CO_2-enriched/ambient-treatment ratio of 1.74.

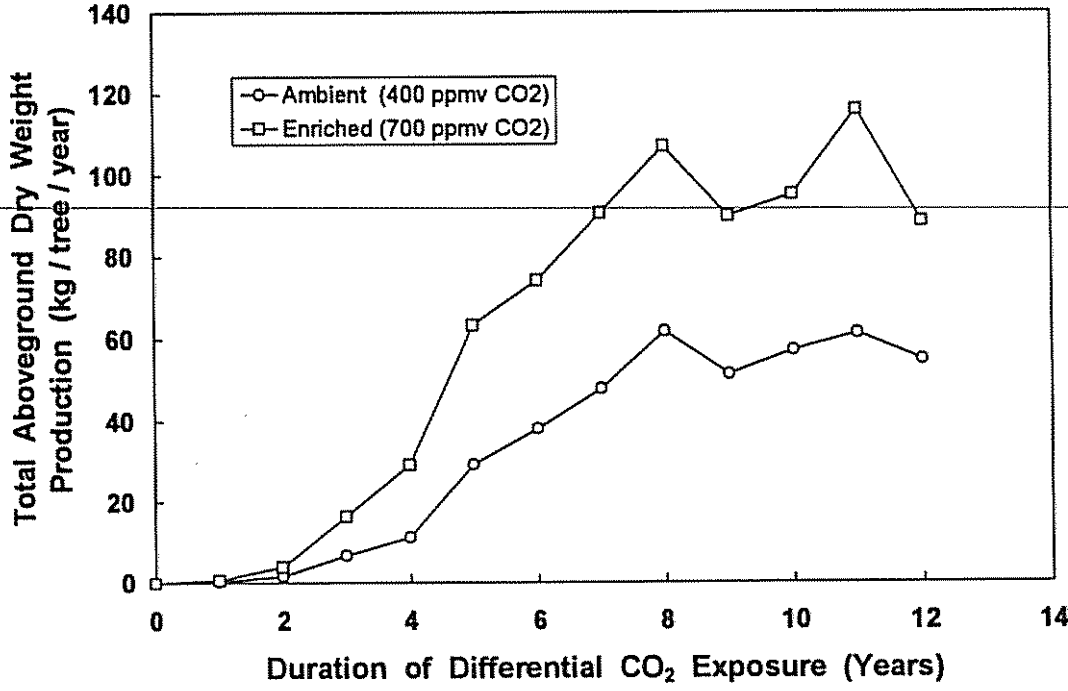

Figure 1. Yearly total aboveground biomass production in the ambient and CO_2-enriched sour orange trees as a function of time since the start of the experiment.

The fruit production component of the total aboveground productivity has been a little more erratic; nevertheless, it too appears to be approaching an asymptotic upper limit (Fig. 2). For the last five years, for example, harvested fruit biomass has been 47, 38, 38, 58, and 36 kg/tree in the CO_2-enriched trees; while in the ambient-treatment trees it has been 25, 13, 23, 31, and 22 kg/tree, producing a five-year-mean CO_2-enriched/ambient-treatment fruit production ratio of 1.87.

We have also discovered that in the spring of each year the CO_2-enriched trees experience an enormous growth enhancement. This initial stimulation begins immediately upon bud-burst; and three to four weeks later, the new branches of the CO_2-enriched trees may be four times more massive than those of the ambient-treatment trees. Furthermore, because there are more branches on the CO_2-enriched trees, they may have as much as six times more total new-branch biomass than the ambient-treatment trees. Shortly thereafter, however, a decline sets in and the CO_2-enriched/ambient-treatment new-branch biomass ratio of the trees ultimately levels out at a

value commensurate with the long-term total aboveground productivity ratio of the CO_2-enriched and ambient-treatment trees; i.e., at a value of approximately 1.74.

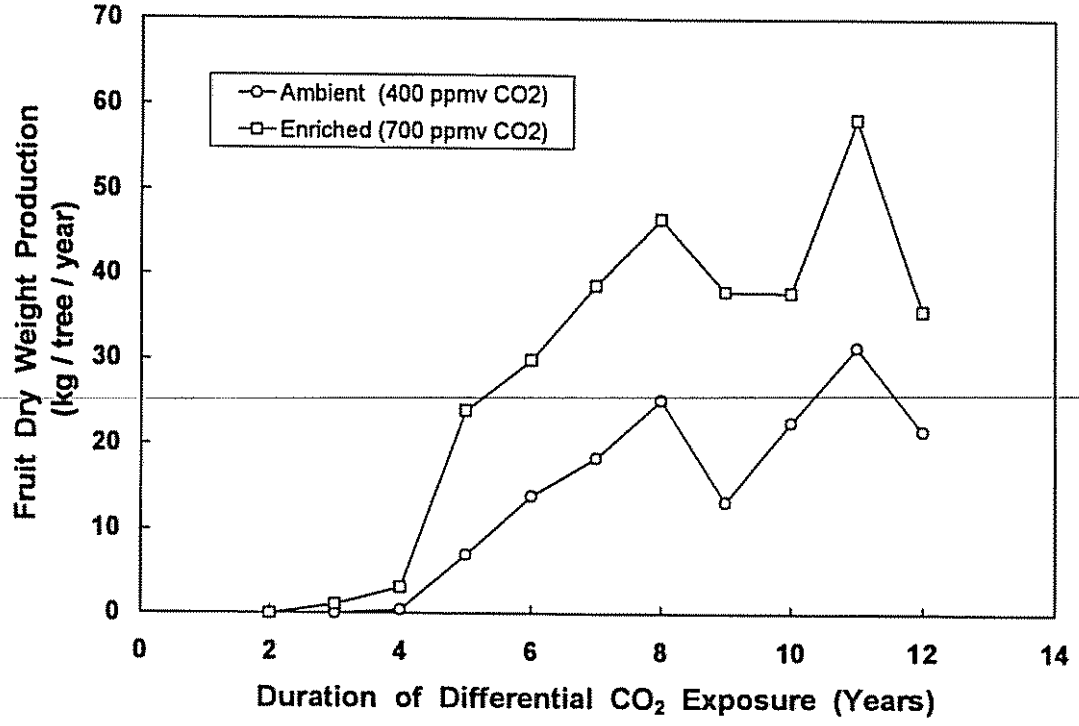

Figure 2. Yearly fruit dry weight production in the ambient and CO_2-enriched sour orange trees as a function of time since the start of the experiment.

INTERPRETATION: What is the ultimate fate of the CO_2 the people of the world yearly emit to the atmosphere? Will the trees of the planet be sufficiently stimulated by the ongoing rise in the air's CO_2 content to remove enough of it from the atmosphere to prevent a significant CO_2-induced warming of the globe? The results of our ongoing study provide important insight into these questions and may help our government craft appropriate policies to meet this global environmental challenge. In the meantime, our findings continue to demonstrate that carbon dioxide is an effective aerial fertilizer, significantly increasing the size, growth rate, and fruit production of sour orange trees exposed to more of this aerial fertilizer than is normally in the air. It is also possible that this phenomenon may be partially responsible for the progressively earlier occurrence of the spring "green up" of the Northern Hemisphere's vegetation, which has been observed over the past few decades in satellite studies of surface reflectance and in the increasingly earlier occurrence of the spring draw-down of the air's CO_2 content that is evident in studies of the atmosphere's seasonal CO_2 cycle (Idso et al., 2000).

FUTURE PLANS: We plan to continue the sour orange tree experiment as long as it takes to determine if the trees truly achieve steady-state yearly growth rates and if the CO_2-enriched trees are maintaining a growth advantage over the ambient-treatment trees that can reasonably be

expected to continue indefinitely. We are also continuing our investigation of the ultra-enhanced spring branch growth phenomenon that we have observed in the CO_2-enriched trees, having just completed three full years of pertinent measurements. In addition, we have initiated several new research thrusts related to the central problem of carbon sequestration. In cooperation with a soil microbiologist, we are investigating the role of atmospheric CO_2 enrichment in stimulating the growth of soil fungi that grow in symbiotic association with the sour orange tree roots and produce a glycoprotein called glomalin, which has been proven to enhance soil aggregation and the stability of soil aggregates. And in cooperation with several scientists who are expert in various types of tree-ring analyses, we are studying cores of the sour orange tree trunks for CO_2-induced differences in cell size, wood density and strength properties. We are also collecting some new data sets that should shed even more light on the effects of atmospheric CO_2 enrichment on the trees' physiology, including weekly assessments of leaf fall and leaf concentrations of chlorophyll, starch and various sugars. Finally, we are entering upon our tenth year of fruit vitamin C measurements and our fourth year of fruit folic acid measurements.

ELEVATED ATMOSPHERIC CO_2 ALLEVIATES WATER-STRESS-INDUCED MID-AFTERNOON DEPRESSION IN WHEAT CARBON GAIN

G.W. Wall, Plant Physiologist; B.A. Kimball, Supervisory Soil Scientist; P. J. Pinter, Jr., Research Biologist; R.L. LaMorte, Civil Engineer; and S.B. Idso, Research Physicist

PROBLEM: Atmospheric CO_2 concentration is on the rise, which can affect stomatal conductance and water absorption processes in wheat (*Triticum aestivum* L.). Elevated CO_2 also affects internal plant water potential, and as is well known, it also affects photosynthesis. The degree to which each of these processes is affected will determine the overall productivity of wheat in the future. An imperative exists, therefore, to determine the effect that a future high CO_2 -world will have on dawn to dusk trends in stomatal conductance (g_s), total (Ψ_W), osmotic (Ψ_π), and turgor (Ψ_P) leaf potentials and net assimilation rate (A) of wheat grown under elevated CO_2 and adequate and limited soil-water content.

APPROACH: A 2-year field study on a hard red spring wheat (cv. Yecora Rojo) crop was conducted in an open field at The University of Arizona Maricopa Agricultural Center located 50 km south of Phoenix, Arizona. Seeds were sown into flat beds at 0.25-m row spacings on December 15, 1992, (130 plants m^{-2}) and December 7-8, 1993 (180 plants m^{-2}). The crops were harvested on May 25-27, 1993, and on June 1, 1994. Following sowing, a free-air CO_2 enrichment (FACE) apparatus was erected on site to enrich the CO_2 concentration of ambient air (~350 μmol mol^{-1}) to 550 μmol mol^{-1} treatment level (main plots) for 24 h per day from 50% emergence until physiological maturity. A subsurface drip-tape irrigation system provided two soil-water content (I) treatments; 50% (Dry) and 100% (Wet) replacement of potential evapotranspiration (split-plot). Treatments combinations, therefore, consisted of Control-Dry (CD), FACE-Dry (FD), Control-Wet (CW) and FACE-Wet (FW). There were four replications of each treatment combination.

A portable closed gas exchange system (0.25 L transparent cuvette) was used to make in situ measurements of g_s and A on uppermost fully expanded sunlit leaves from dawn to dusk. Leaves were excised approximately 5 mm away from the leaf collar to measure Ψ_W with a pressure chamber. Measurements of Ψ_W and Ψ_π were also made at midday with leaf thermocouple psychrometers using standard psychrometric techniques, whereas turgor pressure (Ψ_P) was derived ($\Psi_P=\Psi_W-\Psi_\pi$).

FINDINGS: FACE reduced g_s by 30% at mid-morning (2.5 h prior to solar noon), 34% at midday (solar noon), and 34% at mid-afternoon (2.5 h after solar noon) (Fig. 1). In Dry compared with Wet, FACE caused less of a proportionate reduction in g_s than Control by 2% at mid-morning and midday, but by 25% at mid-afternoon. Full irrigation increased g_s by 66% at mid-morning and midday and 79% at mid-afternoon. Overall, Ψ_W was less negative by 0.16 and 0.33 MPa at midday in FACE compared with Control, and Ψ_W was less negative by 0.25 and 0.59 MPa in Wet compared with Dry during mild (1993) and severe (1994) drought stress years, respectively. Osmotic adjustment ($\Delta\Psi_\pi$) was 0.73 [Ψ_π MPa (Ψ_W MPa)$^{-1}$] for Control and 0.81 [Ψ_π MPa (Ψ_W MPa)$^{-1}$] for FACE (P=0.20), whereas loss of turgor ($\Delta\Psi_P$) was 0.18 [Ψ_P MPa (Ψ_W MPa)$^{-1}$] for Control and 0.16 [Ψ_P MPa (Ψ_T MPa)$^{-1}$] for FACE (P=0.20).

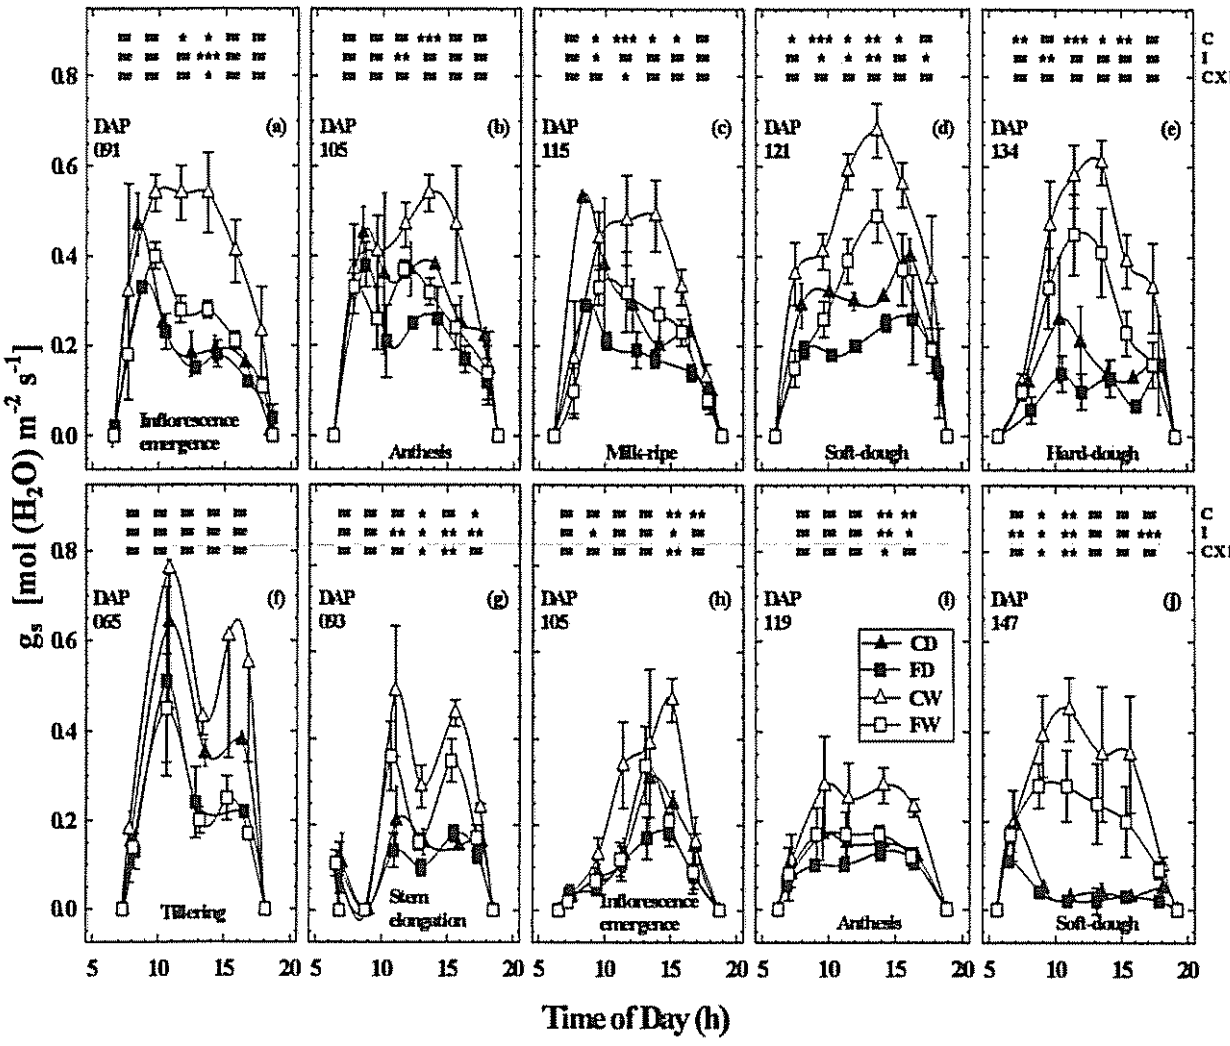

Figure 1. Dawn to dusk trends in stomatal conductance (g_s) of fully expanded sunlit spring wheat leaves for day after planting (DAP) and growth stages given for 5 d during 1993 (a-e) and 1994 (f-j). Symbols in legend refer to Control-Dry (CD), Control-Wet (CW), FACE-Dry (FD), and FACE-Wet (FW) treatments. Each vertical bar is one standard error from each datum. Source of variance in ANOVA are carbon dioxide [(C): Control at 370 μmol mol^{-1}, and FACE at 550 μmol mol^{-1}], irrigation effect [(I): Dry at 50% and Wet at 100% replacement of evapotranspiration], and CxI interaction effects. Significance effects given for each growth stage above each datum as ***, **, *, and ns for $P \leq 0.01$, $P \leq 0.05$, $P \leq 0.10$, and not significant (ne for effect not estimated), respectively. Actual probability of a greater F-value by chance reported if $P \geq 0.10$ and $P \leq 0.25$.

Compared with Control, FACE stimulated A by 32% at mid-morning, 25% at midday,and 23% at mid-afternoon (Fig. 2). The stimulation of A by FACE was greater by 7% at mid-morning and midday and 35% at mid-afternoon under Dry than Wet. Elevated CO_2, therefore, alleviated water-stress-induced mid-afternoon depressions in wheat carbon gain. Full irrigation increased A by 13, 29, and 28% at mid-morning, midday, and mid-afternoon, respectively.

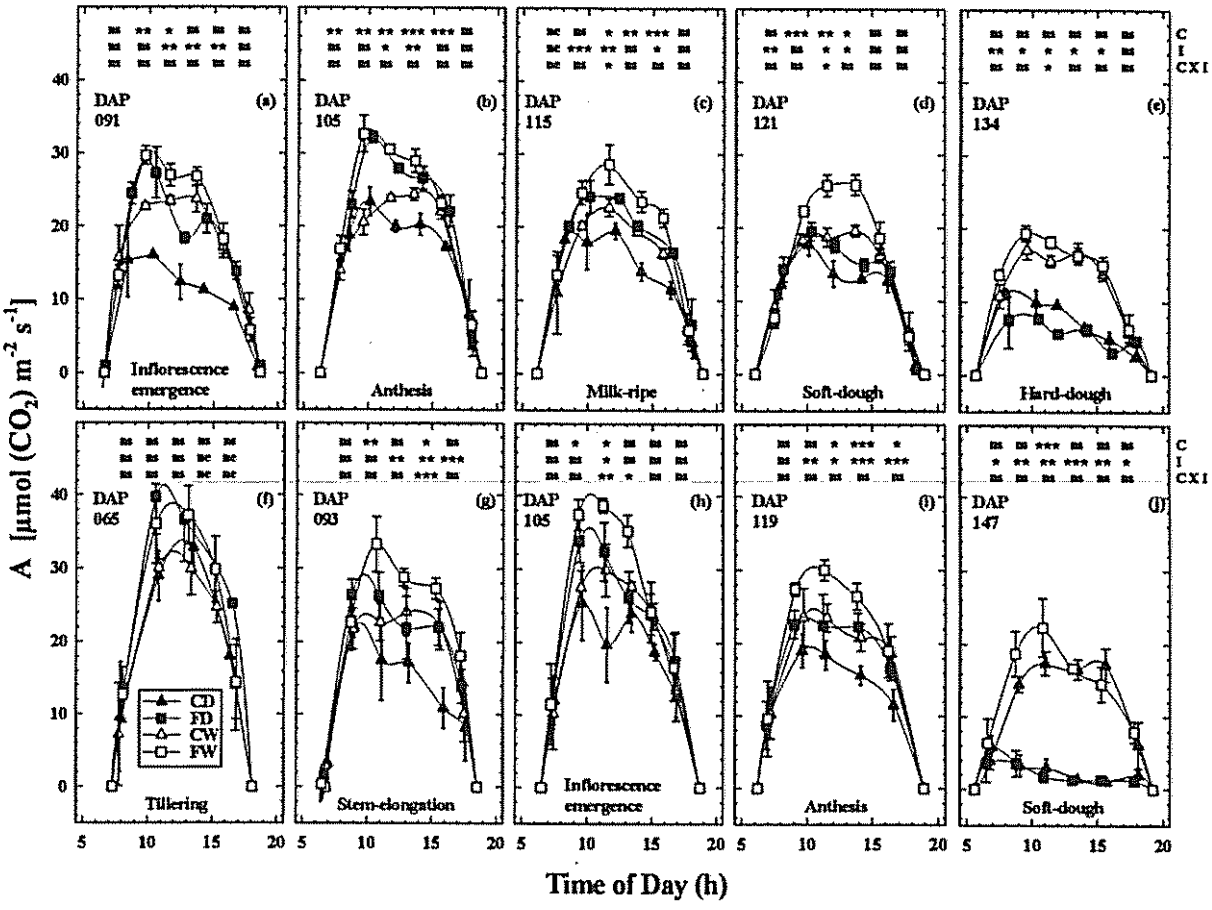

Figure 2. Dawn to dusk trends in leaf net assimilation rate (A) of expanded sunlit spring wheat leaves for day after planting (DAP) and growth stages given for 5 d during 1993 (a-e) and 1994 (f-j). Symbols in legend same as given in Fig. 1. Source of variance and results from ANOVA same as described in Fig. 1.

A hysteresis effect was observed when A vs. photosynthetic photon flux density (PPFD) was plotted from dawn until midday compared to that from midday to dusk (Fig. 3). This hysteresis effect became more pronounced as soil-water content became more depleted. Relationships between A vs. PPFD from dawn to midday and from midday to dusk were normalized (A_n) by dividing each observation of A within a day by the maximum value of A (A_{max}) for that day (usually at mid-morning or midday). Clearly, no hysteresis effect occurred under CW, a slight hysteresis effect was observed under FW, but only a modest increase in this effect was observed for FD. In contrast, a large hysteresis effect was observed for CD (Fig. 3). The smaller the hysteresis effect the greater was daily (A′) and seasonal accumulation (A″) of carbon. Compared with Control, FACE increased A′ and A″ by 25%. However, the stimulation in A″ by FACE over Control was 31% greater under Dry, but only 21% under Wet. This 10% difference in A″ between Dry and Wet can be explained by a proportionate reduction in the hysteresis effect observed for FD compared with CD.

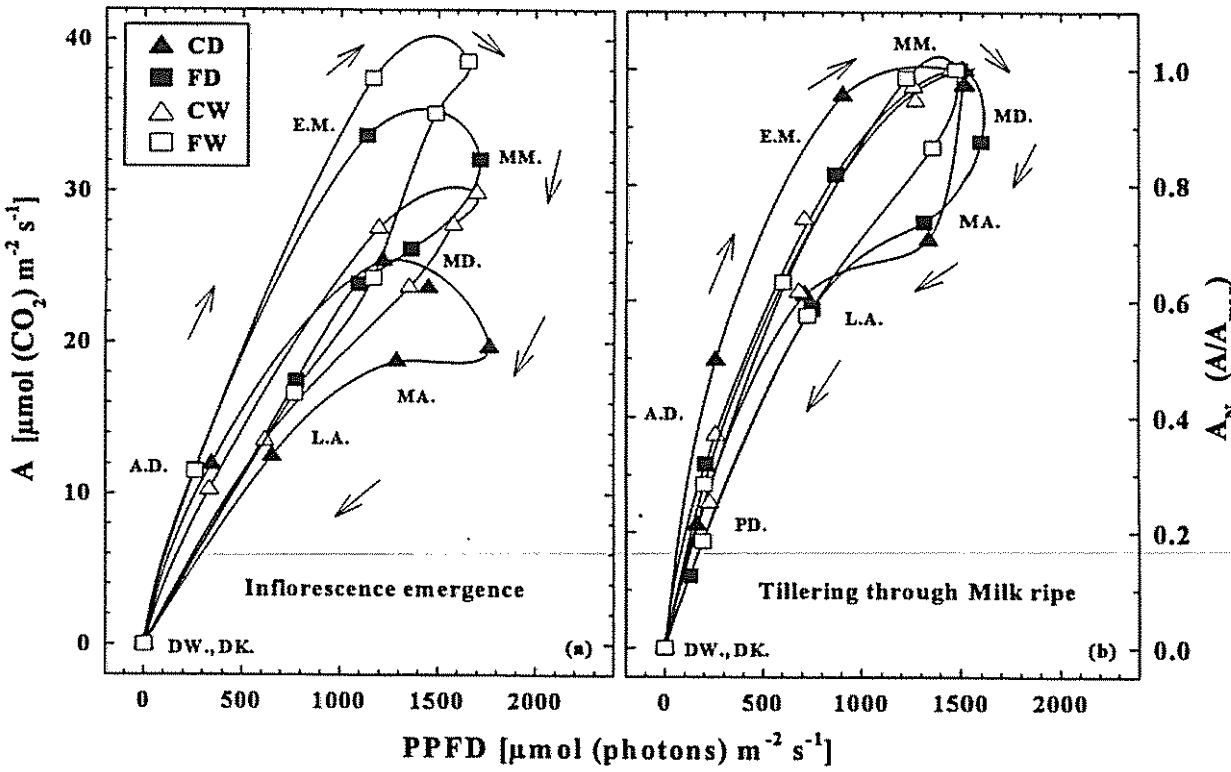

Figure 3: Mean leaf net assimilation rate (A) in response to diurnal course of incident photosynthetic photon flux density (PPFD) during inflorescence emergence on day after planting 105 (replotted from Fig. 2h) (a). Mean normalized leaf net assimilation rate (A_N), across years and growth stages except soft and hard-dough (replotted from Fig. 2a-d and f-i), in response to the diurnal course of incident photosynthetic PPFD (b). Arrows denote direction of hysteresis loop from DW-dawn, AD-after dawn, EM-early morning, MM-mid-morning, MD-midday, MA-mid-afternoon, LA-late-afternoon, PD-pre-dusk, and DK-dusk. Symbol legend same as given in Fig. 1.

INTERPRETATION: Despite the fact that elevated CO_2 directly reduced g_s (Fig. 1), it indirectly increased drought avoidance (reduced evapotranspiration and increased capacity for absorption of water and nutrients by roots), and increased drought tolerance (xeromorphic adaptations and osmoregulation mechanisms). Consequently, as water stress became more severe, the mitigating effect of elevated CO_2 in alleviating drought actually caused a reduction in water-stress-induced stomatal limitation in wheat carbon gain, particularly at mid-afternoon. Nevertheless, these results also demonstrate that although leaves grown under elevated CO_2 will have less stomatal limitations, regardless of water supply, they will still experience some mid-afternoon depression in carbon gain because of non-stomatal limitations (photoinhibition). In a future high-CO_2 world, therefore, additional carbon uptake at mid-afternoon will increase A′ and A″. Presumably, this additional carbon supply will result in an increase in total non-structural carbohydrate pools. Hence, despite any limitations in net primary production because of water deficits, a rise in atmospheric CO_2 will minimize the deleterious effects of drought on physiological function and growth, thereby, expanding the range where a viable crop can be grown, especially under dryland conditions.

FUTURE PLANS: We will continue to analyze, interpret, summarize, and document results from previous FACE experiments on wheat and sorghum. We will also actively plan and seek funding for a FACE alfalfa (*Medicago sativa* L.) experiment (Kimball et al., this volume).

COOPERATORS: See report from Kimball et al., this volume.

REMOTE SENSING CHLOROPHYLL CONTENT IN WHEAT

T. R. Clarke, Physical Scientist; and P. J. Pinter, Jr., Research Biologist

PROBLEM: One of the most important decisions a grower must make is how to manage crop fertilizer inputs in order to assure a profitable yield while preventing groundwater contamination. Variable rate application technology has recently been developed, but the technology for directing applications effectively is less mature. A means of rapidly assessing a wheat crop's fertilizer needs at critical growth stages and at high spatial resolution is needed for this aspect of precision agriculture to succeed.

A second challenge for precision agriculture is a lack of means by which wheat producers can predict grain protein content before harvest with a high degree of spatial resolution. This ability would provide the option of harvesting the highest quality grain separately with the potential of increasing profits.

APPROACH: A Canopy Chlorophyll Content Index (CCCI) that was previously developed for cotton (1999 Annual Report) was tested for wheat using reflectance data collected during the 1997 Free-Air Carbon-dioxide Enrichment (FACE) experiment. The hard red spring wheat *Triticum aestivum* L cv. Yecora Rojo was sown in mid-December 1996 and harvested in late May. Water and fertilizer were applied through a subsurface drip irrigation system. Each of the eight circular experimental plots was split into halves with each half receiving either an ample amount of nitrogen (N) of 383kg/ha/season or a limiting nitrogen treatment of 45 kg/ha/season. Kimball et al. (1999) provide a full description of the FACE experimental design. Hyperspectral canopy reflectance measurements were made at approximately weekly intervals using a field-portable reflectance spectrometer referenced to a $BaSO_4$ panel of known bidirectional reflectance properties. Spectral bands equivalent to those used in the cotton experiment were extracted and used for analysis. These three 10nm-wide bands were Red (R) centered at 670 nm, far-red (F) centered at 720 nm, and near infrared (NIR) centered at 790 nm. Chlorophyll meter (SPAD) measurements of the uppermost fully-expanded leaves were made at about weekly intervals and were used as an estimate of canopy chlorophyll content. Reflectances of the R, F, and NIR bands were combined to produce two variables. The first was the Ratio Vegetation Index (RVI), NIR/R, which is sensitive to the amount of green vegetation present, and the second was the ratio NIR/F, which is sensitive to the chlorophyll content of green vegetation. These two variables were then used as the two dimensions of a plane, and the maximum and minimum measured values for each variable defined the boundaries of a domain within this plane. The position of a coordinate pair within the domain was then correlated to the chlorophyll content as estimated by the SPAD readings.

FINDINGS: A scatter plot of the two variables revealed good separation between low and high N treatments during the early part of the growing season through early stem elongation, and again during early grain filling. During late stem elongation, head emergence, and flowering, there was a distinct drop in far-red reflectance which rendered the planar domain unusable during this period, as seen in Figure 1. Two planar domains were therefore delimited: one for early season through early stem elongation, and a second for milk through early dough stages of grain filling. The early and late planar domains for wheat were used to develop two separate canopy chlorophyll content indices (CCCIwe and CCCIwl). The CCCIwe showed improving
