Consumer Acceptability of Cucumber Pickles Produced by Fermentation in Calcium Chloride Brine for Reduced Environmental Impact

Emily M. Wilson, Suzanne D. Johanningsmeier, and Jason A. Osborne

Abstract: Fermentation of cucumbers in calcium chloride (CaCl₂) brine has been proposed as an alternative process to reduce the environmental impact of traditional, high salt fermentations. The objective of this research was to determine whether consumer acceptability of pickle products would be impacted by fermentation and storage of cucumbers in CaCl₂ brine. Cucumbers were fermented and stored with 0.1M CaCl₂ or 1M sodium chloride (NaCl) in open-air, 3000 gal tanks at a commercial facility and processed into hamburger dill chips containing 0.38M NaCl. Cucumbers fermented in CaCl₂ required additional desalting to reduce CaCl₂ concentrations to that of current products. Consumers (n = 101) showed no significant preference for pickles from different fermentation treatments, whether stored for 2 mo (P = 0.75) or 8 mo (P = 0.68) prior to processing. In contrast, NaCl fermented pickles were preferred over CaCl₂ fermented pickles stored for 10 mo and desalted only once (P < 0.01). A series of preference tests indicated that the taste of CaCl₂ was not the factor affecting consumer preference, and the 50% detection threshold of CaCl₂ in dill pickle chips was found to be 61.8 ± 7.6 mM, indicating that processors could potentially use CaCl₂ fermentations with a single desalting step. Consumer liking of flavor (n = 73) was not influenced by fermentation in CaCl₂ or by 23 or 35 mM CaCl₂ in finished products (P > 0.05), but variability in texture decreased consumer liking (P < 0.05). Although promising, individual fermentation variability and texture quality of CaCl₂ fermented products should be further evaluated prior to broad implementation of this process.

Keywords: calcium chloride taste, cucumber pickles, detection threshold, sodium-free fermentation, sustainability, vegetable preservation

Practical Application: Disposal of high salt waste continues to burden the pickled vegetable industry. Consumer acceptability of pickles produced by commercial fermentation and storage in 1.1% calcium chloride (CaCl₂) brines and traditional 6% sodium chloride brines was evaluated. In 2 independent trials, consumers displayed no difference in preference for pickles produced from either process. Further investigation of the taste of CaCl₂ in finished products suggested that processors may use the CaCl₂ fermentation with their normal process without significant concern for alterations in the taste profile. However, variability in texture quality impacted consumer acceptability, indicating the need for further process optimization.

Introduction

In the United States, more than 800 million kg of fermented vegetables are produced annually (Hutkins 2006). In fact, the pickled vegetable market accounts for more than $2 billion, with fermented cucumber pickles constituting one of the primary products (Doyle and Beuchat 2007). Pickling cucumbers are commercially fermented in 40000 L open-top, plastic, or fiberglass tanks with a minimum of 5% sodium chloride (NaCl) in the fermentation brine (Franco and others 2012). Most commercial fermentation processes occur under conditions of high salt concentration, which allows for a natural fermentation by indigenous, homofermentative, lactic acid bacteria present on the surface of cucumbers (Ettchells and Jones 1946; Fleming and others 1992). Only 2% to 3% NaCl is desired in the finished product, which results in the need to desalt the fermented cucumbers prior to packing the finished product (Fleming 1984). Waste waters from this process are high in sodium chloride and biological oxygen demand representing a significant waste treatment challenge for processors (Little and others 1976).

Fermentation of cucumbers with 0.1 M calcium chloride (CaCl₂) instead of the traditional 1.03 M (6 %) NaCl has been successfully applied on a controlled, experimental scale as a means to combat the environmental issues and toxic effects associated with the large amounts of NaCl in pickle plant waste waters (McFeeters and Pérez-Díaz 2010). Recent research (Pérez-Díaz and others unpublished) demonstrated the potential for stable commercial cucumber fermentations using CaCl₂ and a starter...
Consumer acceptability of cucumber pickles

that are concentrations in finished pickle products and whether the consumers had differences in preference between products from the 2 fermentation processes for fermentation and bulk storage. The fermented cucumbers were stored for either 2 or 8 mo of bulk storage before processing into finished products. All finished products had a shelf storage time of 12 mo before sensory evaluation. Panelists (n = 101, 56 female) were distributed across the following age divisions: 18 to 25 (49%), 26 to 35 (22%), 36 to 45 (12%), 46 to 55 (12%), and 56 to 65 (6%). Sixty-eight percent of respondents were Caucasian. Pickle consumption demographics fell mainly into 4 categories: several times per week (21%), once a week (27%), 2 to 3 times per month (32%), and once a month (11%). Results from 10 and 9 panelists were omitted from the 2 and 8 mo preference test results, respectively, because of the panelists expressing no preference. Panelists were presented with 2 pairs of samples using a randomized complete block design. Samples in each pair were commercially processed to reach equivalent salt and acid compositions upon equilibration. The pairs, differing by independent fermentations, storage time in the tank yard, and desalting involved a traditional NaCl fermentation treatment and a CaCl₂ fermentation treatment that contained equilibrated CaCl₂ concentrations of 18.7 ± 2.5 mM and 24.1 ± 1.3 mM for the 2 and 8 mo pairs, respectively. Panelists were instructed to taste the samples from left to right and indicate which sample they preferred in each pair or if they had no preference.

### Materials and Methods

Fermentation and sample processing

Cucumbers of size 2B (32 to 38 mm in diameter) or 3A (39 to 51 mm in diameter) were fermented in either 1.03M NaCl or 0.1M CaCl₂ in a commercial tank yard in open-top, 10,000 L polymer tanks. Fermented cucumbers collected from at least 3 feet below the surface of the brine were desalted to equilibrium prior to processing with distilled water in a 60:40 cucumber to water ratio. A 2nd desalting step at a 60:40 cucumber to water ratio, followed completion of the 1st desalting for selected treatments. Desalted, fermented cucumbers were sliced into 3 to 6 mm hamburger dill chip rounds, packed into 16-oz glass jars with a traditional commercial brine formula for hamburger dill chips (58:42, cucumber to brine pack-out ratio), pasteurized in a commercial tunnel pasteurizer according to manufacturers specifications, and stored at room temperature (23 ± 2 °C) under ambient lighting. All finished products contained an equilibrated NaCl concentration of 0.38 ± 0.03M, 96 ± 10 mM acetic acid added as vinegar, and 21 ± 6 mM lactic acid from fermentation. The proportion of brine to cucumbers in each jar may vary up to 5% in the commercial setting. However, jar to jar variation was controlled to <0.5 % in finished products packed by the researchers. CaCl₂ was the only constituent of the brine that was intentionally modified for each treatment; concentration of CaCl₂ in finished products was quantified by titration with EDTA using bromocresol blue as an indicator (AOAC Official Method 968.31).

Panelist selection and testing environment

Subjects 18 years or older were recruited from the North Carolina State Univ. (NCSU) community for each of the experiments outlined in this study under approval from the NCSU Institutional Review Board (IRB #3092, 2192, and 2971), and informed consent was obtained from all participants. For all experiments, 2 hamburger dill chip slices from each jar were served at room temperature in 2-oz plastic souffle cups with lids (Solo cup, Highland Park, Ill., U.S.A.) labeled with random 3-digit codes. The 3-digit sample codes and sample order were randomized among panelists. Room temperature distilled water and unsalted crackers were provided to cleanse the palate between samples.

Paired preference testing of commercial products

The goal of these tests was to determine whether pickle consumers had differences in preference between products from the 2 fermentation brining processes when the finished product CaCl₂ concentration was maintained at typical levels of 18 to 25 mM. Finished cucumber pickle products were obtained from 2 independent, commercial trials comparing the CaCl₂ and NaCl brining processes for fermentation and bulk storage. The fermented cucumbers were stored for either 2 or 8 mo of bulk storage before processing into finished products. All finished products had a shelf storage time of 12 mo before sensory evaluation. Panelists (n = 101, 56 female) were distributed across the following age divisions: 18 to 25 (49%), 26 to 35 (22%), 36 to 45 (12%), 46 to 55 (12%), and 56 to 65 (6%). Sixty-eight percent of respondents were Caucasian. Pickle consumption demographics fell mainly into 4 categories: several times per week (21%), once a week (27%), 2 to 3 times per month (32%), and once a month (11%). Results from 10 and 9 panelists were omitted from the 2 and 8 mo preference test results, respectively, because of the panelists expressing no preference. Panelists were presented with 2 pairs of samples using a randomized complete block design. Samples in each pair were commercially processed to reach equivalent salt and acid compositions upon equilibration. The pairs, differing by independent fermentations, storage time in the tank yard, and desalting involved a traditional NaCl fermentation treatment and a CaCl₂ fermentation treatment that contained equilibrated CaCl₂ concentrations of 18.7 ± 2.5 mM and 24.1 ± 1.3 mM for the 2 and 8 mo pairs, respectively. Panelists were instructed to taste the samples from left to right and indicate which sample they preferred in each pair or if they had no preference.

Consumer testing of small-scale experimental products

Small-scale experimental products were created to evaluate whether higher residual calcium levels would influence consumer preference. Commercially fermented cucumbers were processed, after a 9 to 10 mo bulk storage time, in a food grade pilot plant, packed in 16-oz glass jars, pasteurized at 75 °C for 15 min, and stored under ambient conditions until testing. The 4 treatments, CaCl₂ 1 desalt, CaCl₂ 2 desalt, NaCl traditional, and NaCl with elevated CaCl₂, contained 36, 28, 20, and 34 mM CaCl₂, respectively.

A paired, A-Not A difference test (Bi and Ennis 2001) was performed in isolated booths at the NCSU sensory testing facility.
(Dept. of Food, Bioprocessing, and Nutrition Sciences, NCSU, Raleigh, N.C., U.S.A.). Panelists (n = 50, 34 female) were distributed across the following age divisions: 18–25 (36%), 26–35 (34%), 36–45 (8%), 46–55 (12%), 56–65 (8%), and 66+ (2%). Seventy-four percent of panelists consumed pickles on a monthly or weekly basis. The A-Not A testing procedure was performed as outlined in ISO 8588:1987 (E). The 2 samples included a traditional NaCl fermented treatment (A) and a CaCl₂ fermented 1 desalt treatment (Not A). An A and Not-A reference sample was presented to each panelist for an unlimited amount of time. When prompted by the panelists, the reference samples were removed and not returned. Then, 2 samples were presented to the panelists one at a time in a random order, with an equal distribution of 2 presentations: “A” followed by “Not A” or “Not A” followed by “A.”

Paired preference testing was performed at individual stations set up in a classroom with ambient temperature and lighting (NCSU, Dept. of Food, Bioprocessing, and Nutrition Sciences). All paired preference tests presented panelists with 2 pairs of samples in a randomized complete block design. In Paired Preference Test 1, the 2 sample pairs were: (1) NaCl traditional treatment versus CaCl₂ one desalt treatment and (2) NaCl traditional treatment versus CaCl₂ 2 desalt treatment. Panelists (n = 50, 32 female) were distributed across the following age divisions: 18 to 25 (34%), 26 to 35 (30%), 36 to 45 (12%), 46 to 55 (16%), 56 to 65 (6%), and 66+ (2%). Eighty-four percent of panelists consumed pickles on a monthly or weekly basis. Results from 7 and 4 panelists were omitted from pair 1 and 2, respectively, because of the panelists expressing no preference. For Paired Preference Test 2, the 2 sample pairs were: (1) NaCl fermented treatment with elevated CaCl₂ versus NaCl traditional treatment and (2) NaCl fermented treatment with elevated CaCl₂ versus CaCl₂ one desalt treatment. Panelists (n = 50, 37 female) were distributed across the following age divisions: 18 to 25 (38%), 26 to 35 (26%), 36 to 45 (12 %), 46 to 55 (14%), 56 to 65 (8%), and 66+ (2%). Eighty-eight percent of panelists consumed pickles on a monthly or weekly basis. Results from 3 and 2 panelists were omitted from pair 1 and 2, respectively, because of the panelists expressing no preference.

Consumer liking of commercial products

A hedonic evaluation of products was used to gather additional information on the acceptability of CaCl₂ brined, fermented cucumber pickles finished to varying residual calcium levels. Cucumbers were commercially fermented and bulk stored in the tank yard 4 mo before processing into finished products; finished products were stored under ambient conditions for 2 mo before evaluation. Panelists (n = 73, 51 female) were distributed across the following age divisions: 18 to 25 (48%), 26 to 35 (21%), 36 to 45 (16 %), 46 to 55 (10%), and 56 to 65 (5%). Eighty percent of consumers participating in the liking test consumed pickle products at least monthly, with 40% having a consumption frequency of weekly or greater. However, purchase frequency was lower than consumption frequency, with 41% of consumers purchasing pickle products no more than several times per year. The consumers in this study reported that flavor and texture were the primary factors influencing purchasing intent, more so than cost or brand. Panelists were presented with 4 treatments in a randomized complete block design. Treatments differed by fermentation brining salt and the concentration of CaCl₂ in finished products: NaCl fermented traditional (23 mM CaCl₂), NaCl fermented with elevated CaCl₂ added to finished product (35 mM CaCl₂), CaCl₂ fermented 1 desalt (35 mM CaCl₂), and CaCl₂ fermented 2 desalt (23 mM CaCl₂). Panelists were asked to rate their overall liking, as well as flavor, texture, and appearance liking on a hedonic scale, with 1 and 9 corresponding to dislike extremely and like extremely, respectively. In addition, panelists were given the option of commenting on what they liked most or least about the samples for each of the 4 categories.

Texture analysis

Mesocarp firmness of fermented hamburger dill pickle chips was measured using a TA.XT2 Texture Analyzer (Texture Technologies Corp, Scarsdale, N.Y., U.S.A./Stable Micro Systems, Godalming, Surrey, UK) equipped with a 3-mm-diameter punch probe. Methodology was performed as outlined in Thompson and others (1982) and Yoshioka and others (2009). Briefly, pickle slices were placed onto a base plate containing a 3.1-mm hole. The punch probe moved at a test speed of 2.5 mm/s. Data were collected and analyzed using Texture Expert software (Texture Technologies Corp./Stable Micro Systems). The peak force required to puncture the mesocarp was recorded and expressed in Newtons (N). Firmness measurements were done at ambient temperature (23 ± 2 °C) on 15 slices from each of 2 jars of each treatment. Average peak force from the 15 slices was subjected to statistical analysis.

Color analysis

The L∗, a∗, b∗ values of hamburger dill pickle chips evaluated in the liking test were measured using a Minolta Chroma Meter model CR-300 (Minolta Co., Ltd., Osaka, Japan). Because of the transparency of pickle chips, 10 pickle chips were stacked on top of each other and measurements were taken of the mesocarp of the top slice. An average of 10 pickle chip measurements per treatment was reported.

Detection threshold of CaCl₂ in hamburger dill pickle chips

Cucumbers were commercially fermented in a NaCl brine and stored in bulk for 4 mo before processing into finished products. The cucumbers were desalted to equilibrate to a NaCl concentration of 2.2% in finished products. Pickles were packed in a commercial facility with cover brines formulated to deliver equilibrated CaCl₂ concentrations of 26, 36, 50, 70, and 98 mM CaCl₂ to allow for performance of a 5-series threshold test with a step-factor of 1.4. Concentrations were selected to include values surrounding the legal limit for CaCl₂ in pickle products, and the step factor was based on preliminary trials. A modified blank sample containing a CaCl₂ concentration of 21 mM was chosen to represent the typical level in commercially available hamburger dill chip pickles. Finished products were stored under ambient conditions for 2 mo prior to evaluation. The threshold testing procedure outlined in ASTM standard E679 (2011) was followed with a 2 min forced break between each of the 5 rows. The ballot contained an optional section for comments on the description of the taste difference within each of the 5 rows. Panelists (n = 52, 30 female) were distributed across the following age divisions: 18 to 25 (56%), 26 to 35 (12%), 36 to 45 (10 %), 46 to 55 (13%), and 56 to 65 (10%). Eighty-eight percent of panelists consumed pickles on a monthly or weekly basis.

Statistical analyses

Data were collected using paper ballots and compiled in an electronic spreadsheet. All results were analyzed using SAS statistical software (version 9.3, SAS Inst. Inc., Cary, N.C., U.S.A.).

Preference tests were analyzed using a χ² test and an α level of 0.05. For all preference tests, a no preference option was allowed and the most powerful data analysis option of dropping the no preference votes was applied (Ennis and Ennis 2012). Data were later analyzed by splitting the no preference votes with no significant difference (P > 0.05) in the results, supporting the decision to drop no preference votes from the dataset. Consumer liking data were analyzed by repeated measures ANOVA and Tukey’s honestly significant difference post hoc test. In addition, a statistical power test was performed (α = 0.05) before conducting the liking test with an estimated standard deviation of 2.2; 72 panelists were needed to detect a 1 point difference in means with 80% power.

The CaCl₂ detection threshold was determined using both the ASTM E679 method and the alternative method for threshold data analysis developed by Lawless (2010), which involves plotting the chance-corrected proportion of detection on the y-axis and CaCl₂ concentration on the x-axis and interpolating the threshold concentration of CaCl₂ at different detection levels. Subjects (n = 52) were recruited to obtain sufficient statistical power (approximately 80%) based on the statistics of a 1-sample t-test, an expected mean deviation of 9 and a standard deviation of 22. In addition, the GLIMMIX procedure in SAS (SAS version 9.3, SAS Inst., Inc.) was used to fit a generalized linear mixed model appropriate for the dichotomous response. This model had fixed quadratic effects for CaCl₂ concentration, random panelist effects, and an intercept fixed at β₀ = −log(2) to constrain the probability of guessing for undetectable changes in CaCl₂ concentration to π = 1/3 at a CaCl₂ concentration of 0.

Results and Discussion

Paired preference testing of CaCl₂ and NaCl fermented cucumber pickles

In 2 independent commercial trials, no significant preference was observed between CaCl₂ and NaCl fermented cucumber pickles, regardless of the tank yard storage time of 2 mo (χ² = 0.10, P = 0.75) or 8 mo (χ² = 0.17, P = 0.68; Table 1). These results showed that consumers (n = 101) did not have a significant preference between products from the 2 fermentation brining processes when the finished product CaCl₂ concentration was maintained at typical levels of 18 or 25 mM. This finding suggests that it is possible for cucumbers to be fermented and stored in CaCl₂ brines in a commercial setting without a negative impact on consumer acceptability. Samples evaluated in these tests were collected from different fermentation tanks stored for different periods of time in the tank yard, but neither of these variables had an effect on consumer preference of finished products. In contrast, consumers could differentiate between a traditional NaCl fermented pickle (χ² = 6.48, P = 0.01) and CaCl₂ brined cucumber pickles with higher residual CaCl₂ content in an A—Not A Difference Test (χ² = 15.68, P < 0.0001; Table 1). Because of the inherent variability of pickles, even within the same treatment, the question was posed as to whether or not the consumer would show an overall preference for one treatment over the other, regardless of whether they were able to detect a difference. Therefore, preference tests were performed between the NaCl traditional treatment and the CaCl₂ fermented cucumber pickles processed with 1 or 2 desalting treatments to determine if an additional desalt step for the CaCl₂ fermented cucumbers was necessary for consumer preference. In these paired preference tests, the NaCl fermented treatment was preferred over both of the finished products from this particular CaCl₂ fermentation, regardless of the extent of desalting (P < 0.05; Table 1). The significant preference for NaCl fermented cucumber pickles over the CaCl₂ 2 desalt treatment was especially unexpected, as it appears to contradict the results from the 2 preference tests on commercial products. However, a number of factors aside from the potential adverse taste of elevated levels of CaCl₂ may influence consumer preference, such as the inherent fermentation variability encountered when experimenting with cucumbers fermented on a commercial scale in open-top fermentation tanks or variations in fermented and bulk stored cucumbers because of the difference in salt brining treatment. These particular fermentations had been in bulk storage in the tank yard for 9 to 10 mo. Further testing was conducted to determine whether the observed difference in preference was influenced primarily by the difference in CaCl₂ content in finished products.
Fermented cucumbers collected from the same NaCl fermentation tank as above were processed into products in which the only difference was the level of CaCl₂ in finished products, either 20 or 34 mM, and consumers expressed no significant preference between the products ($\chi^2 = 0.02, P = 0.88$; Table 1). However, when the level of CaCl₂ in finished products of both NaCl and CaCl₂ fermented cucumbers was equivalent, 35 ± 1 mM, and the only difference was the fermentation salt and tank from which the pickles were collected, consumers expressed a significant preference for the NaCl fermented product ($\chi^2 = 5.33, P = 0.02$). Therefore, it appears that when CaCl₂ is present in hamburger dill chip pickles at levels around the legal limit of 36 mM, the resulting taste and texture due to the elevated CaCl₂ is not responsible for the observed difference in consumer preference between the traditional hamburger dill chip product and the experimental CaCl₂ fermented product desalted only once. Rather, inherent variability related to fermentation and long-term bulk storage or differences because of brining salt treatment were likely influencing consumer preference in this particular comparison.

*Liking rated on a hedonic scale (1 = dislike extremely; 9 = like extremely); Means with the same letter (a–b) are not significantly different (Tukey’s honestly significant difference, $P < 0.05$).

Fermented cucumbers collected from the same NaCl fermentation tank as above were processed into products in which the only difference was the level of CaCl₂ in finished products, either 20 or 34 mM, and consumers expressed no significant preference between the products ($\chi^2 = 0.02, P = 0.88$; Table 1). However, when the level of CaCl₂ in finished products of both NaCl and CaCl₂ fermented cucumbers was equivalent, 35 ± 1 mM, and the only difference was the fermentation salt and tank from which the pickles were collected, consumers expressed a significant preference for the NaCl fermented product ($\chi^2 = 5.33, P = 0.02$). Therefore, it appears that when CaCl₂ is present in hamburger dill chip pickles at levels around the legal limit of 36 mM, the resulting taste and texture due to the elevated CaCl₂ is not responsible for the observed difference in consumer preference between the traditional hamburger dill chip product and the experimental CaCl₂ fermented product desalted only once. Rather, inherent variability related to fermentation and long-term bulk storage or differences because of brining salt treatment were likely influencing consumer preference in this particular comparison.

**Consumer liking of commercially fermented products**

To further investigate the consumer acceptability of the cucumber pickles fermented in 1.1% CaCl₂ brines, a consumer liking test was conducted on hamburger dill chips prepared from NaCl or CaCl₂ fermented cucumbers stored for only 4 mo in bulk storage before processing into finished products with 23 or 35 mM CaCl₂ and 0.38 M NaCl. Interestingly, the CaCl₂ fermented products were less well liked overall ($P < 0.05$). Flavor, however, was the only category in which the liking scores did not differ ($P > 0.05$) among the treatments (Figure 1), supporting the results from paired preference testing, in which the elevated level of residual CaCl₂ did not affect consumer acceptability of the finished products, regardless of individual fermentation variability or salt brining treatment. The lack of difference in consumer liking of flavor within either fermentation brining treatment, regardless of extent of desalting, suggests that there is no practical benefit in additional desalting to reduce fermentation flavors or to reduce the CaCl₂ concentration.

However, consumers gave higher scores for texture and appearance liking ($P < 0.05$) to the 2 NaCl fermented pickles over the CaCl₂ fermented pickles (Figure 1). In addition, approximately 20% of the respondents commented negatively about the “softness” or “lack of crispiness” for these CaCl₂ fermented cucumbers, regardless of CaCl₂ concentration in the finished product. The significantly lower firmness of CaCl₂ fermented pickles was confirmed through instrumental texture analysis (Table 2), showing a strong trend between reduced mesocarp firmness and consumer liking of texture. The significantly lower liking scores associated with the appearance of the CaCl₂ fermented pickles was further evaluated through the use of colorimetric analysis, in which the

*Liking rated on a hedonic scale (1 = dislike extremely, 9 = like extremely); means with the same letter (a–b) are not significantly different (Tukey’s honestly significant difference, P < 0.05).

L* values were found to be greater (P < 0.05) and a* values more negative (P < 0.05) for CaCl₂ fermented pickles (Table 3).

Detection threshold of CaCl₂ in hamburger dill chip pickles

The detection threshold of CaCl₂ in NaCl fermented hamburger dill pickle chips as determined by the ASTM E679 calculation method for the best estimate threshold (BET) was 53 ± 22 mM. Despite the high standard deviation, the statistical power of this test was still above the desired 80% power. Because of the limitations of the ASTM method, Lawless (2010) developed an alternative method in which the chance-corrected percent correct for each concentration of CaCl₂ in the 5 rows is plotted using an ordinary least squares regression (OLS). In turn, the threshold concentration at varying detection levels can be interpolated. The OLS equation for this data set was $y = 0.92x + 7.54$, $R^2 = 0.96$, where $y$ is the chance-corrected percent correct and $x$ is the concentration of CaCl₂ in finished hamburger dill chip products (Figure 2). This method of threshold calculation is particularly useful, as it allows one to determine the detection threshold at any given level of detection, not just 50%. For example, pickle processors can determine the detection threshold of CaCl₂ in hamburger dill chips at a more conservative level, such as the concentration at which 25% of the population will be able to detect CaCl₂ in hamburger dill chips. Using this equation, the 10%, 25%, and 50% detection levels were 34.8, 46.0, and 64.1 mM CaCl₂, respectively (Figure 2). The ability to estimate confidence intervals accounting for the panelists as random variables was accomplished using a logistic regression model with a quadratic fit and forced intercept to represent the chance probability of 1/3 for undetectable levels of CaCl₂. This model produced similar estimates for 10%, 25%, and 50% detection levels, 39, 49.2, and 61.8 mM, respectively, with the greatest difference observed at the low levels of detection that are near the legal limit for CaCl₂ in finished pickle products (Table 4). Regardless of method of calculation, the 50% detection threshold of CaCl₂ in fermented hamburger dill chip pickles was greater than the highest concentration that is legally allowed in fermented vegetables (36 mM). However, the modeling of the taste threshold for CaCl₂ in fermented pickle products has not been previously reported, and a small proportion of the population, approximately 10%, may be capable of detecting the presence of elevated CaCl₂ concentrations of 36 mM in cucumber pickles. CaCl₂ is a commonly used minor ingredient in both fermented and fresh-pack cucumber pickles. According to Buescher and others (2011), the residual calcium concentration in traditional commercial dill pickles has increased to about 17 mM on average. However, the effect of elevated calcium concentration on the consumer acceptability of cucumber pickles was previously unknown. One of the major concerns for pickle processors when considering a CaCl₂ brine for fermentation is the potentially adverse taste related to a higher CaCl₂ concentration in finished products. It was
hypothesized that no significant difference or preference would be found between the traditional NaCl fermented products and the CaCl₂ fermented products receiving either one desalting step or 2 desalting steps before processing because of the taste interactions of the main components of pickle products, acetic acid and NaCl with CaCl₂. This research showed that residual CaCl₂ levels up to the legal limit of 36 mM in pickled vegetable products did not significantly influence consumer preference or consumer liking of flavor in fermented hamburger dill chip pickles (Table 1; Figure 1). In addition, the 50% detection threshold of CaCl₂ was found to be well above 36 mM in fermented hamburger dill chip pickles (Table 4). In turn, processors may choose to adopt the CaCl₂ fermentation process with the typical desalting practices without concern for the effect of elevated CaCl₂ concentrations up to the maximum legal concentration of 36 mM. However, the detection threshold of consumers tends to be extremely variable around what is considered to be sub-threshold or threshold concentrations. If a processor wanted a more conservative estimate to target even the most sensitive consumers, a finished product CaCl₂ concentration of approximately 28 mM is suggested, using the alternative threshold method (Figure 2), or 25 mM to be below the 95% confidence interval for detection by 10% of the population. Significant preferences were observed in the preference testing of small-scale experimental products, but not in relation to residual CaCl₂ concentration. When CaCl₂ concentration was kept constant in both the small-scale experimental products and large-scale commercially packed products, seemingly conflicting results were obtained for consumer preference (Table 1). Similarly, although consumers showed no significant preference (P > 0.05) between a NaCl fermented traditional treatment and a CaCl₂ 2 desalt treatment in commercially packed products, significant preference (P < 0.05) was observed between these 2 treatments in the trials involving small-scale experimental products (Table 1). Samples varied with regards to cucumber origin, the season in which fermentation began, storage time in the tank yard prior to processing into finished products, the individual fermentation tanks from which the cucumbers were collected, the extent of desalting, and the use of alum during desalting. The conflicting preference test results highlight the degree to which the inherent fermentation variability in commercial tank yards may influence the quality of finished products and ultimately may affect consumer preference.

Although no significant difference (P > 0.05) in consumer acceptability of flavor of the CaCl₂ and NaCl fermented products was expressed in the consumer liking test of commercially packed products, regardless of residual CaCl₂ levels in finished products, texture differed significantly (P < 0.05). In contrast to earlier work completed by Buescher and others (2011) in which CaCl₂ increased mesocarp crispness, consumers from the liking test noted that both of the CaCl₂ fermented treatments were “soft” or “less crisp” and scored the CaCl₂ fermented treatments significantly lower in texture liking (P < 0.05), regardless of residual CaCl₂ levels (Table 2). One possible explanation for the reduced texture quality of these CaCl₂ fermented products involves the potential role of polygalacturonase (PG), a ripening/softening enzyme known to be present in cucumber fruits (Bell and others 1950; McFeeters and others 1980; Cho and Buescher 2012). Bell and Etchells (1961) showed that firmness of cucumber pickles with a NaCl concentration of 0% was reduced by more than 80% after only 1 week of incubation at 30 °C because of the PG enzyme. Furthermore, although Buescher and others (1979) demonstrated that 100 mM CaCl₂ can inhibit the softening activity of the PG enzyme in both high salt (9.0% NaCl) and low salt (4.5% NaCl) fermentation brines, a lower firmness was observed in the low salt treatments. Therefore, the lack of NaCl in the CaCl₂ fermentation brines may be allowing increased activity of the native PG enzyme, resulting in textural defects after long term storage. Lu and others (2002) showed that the composition and structure of the cucumber fruit itself is variable among different sizes and cultivars, which may further contribute to variations in texture quality of finished products. Lastly, despite the common use of alum in the desalting waters of commercial pickle plants, the research samples did not include alum, to avoid introducing another variable. There is some interest in the pickle industry to remove alum from the desalting waters because of health concerns, but the removal of alum may result in a significant decrease in texture quality of finished products. Further studies are needed to determine if including alum in desalting waters plays a crucial role in retaining the texture of finished pickle products fermented and stored in the absence of NaCl.

Consumer acceptability was also somewhat influenced by the appearance of the cucumber pickles. Although the same concentration of yellow 5 was added to all of the treatments, the resulting color was significantly different among the treatments. CaCl₂ fermented products were found to have significantly higher L* values (P < 0.05), indicating a lighter colored product, and significantly more negative a* values (P < 0.05), indicating a stronger green color (Table 3). Lawrence and others (2003) hypothesized that a high concentration of calcium ions may induce pro-oxidation effects similar to iron or copper ions after discovering that a 100 to 300 mM CaCl₂ marinated resulted in steaks that were less red than those marinated in calcium lactate. The pro-oxidation effects seemingly associated with CaCl₂ may actually be related to the impurity of CaCl₂ being used (94% pure in these commercial trials), in which trace metal contaminants could be involved in initiating oxidation. Another possible explanation for the difference in color may be related to the reduction in texture quality associated with these particular cucumbers fermented in CaCl₂. The physicochemical changes that resulted in reduced texture quality may also impact the interaction between the product and light, resulting in changes in color perception by consumers. Further research is needed to understand the basis for the observed differences in appearance of CaCl₂ fermented cucumber pickles.

**Conclusion**

Although a difference was observed between CaCl₂ and NaCl fermented pickles processed with one desalting step, pair-wise
preference testing showed that the taste of CaCl₂ was not the factor affecting consumer preference. This finding was further supported by the calculated 50% detection threshold of CaCl₂ in hamburder dill chip pickles of 61.8 ± 7.6 mM, which is well above the legal limit of 36 mM for pickled vegetable products. In addition, there was no difference in flavor liking between NaCl and CaCl₂ fermented products finished with varying levels of calcium chloride, suggesting that processors could employ CaCl₂ fermentations with a single desalting step without concern for the adverse taste of elevated levels of CaCl₂. Variability in consumer acceptability of CaCl₂ fermented pickles indicated that flavor stability during bulk storage, differences in product appearance, and texture quality of CaCl₂ fermented products should be further evaluated before broad implementation of this process.

Acknowledgments

The authors thank Mount Olive Pickle Company and Lisa Moeller for donation of resources and expertise, Pickle Packers Intl., Inc., for partial financial support, Lisa Rosenberg for assistance in performing sensory tests, D. Seth Fornea for texture and color analysis of selected samples, and Janet Hayes for microbiological testing of products prior to consumption.

Authors’ Contributions

E.M. Wilson designed the experiments, conducted the sensory research, analyzed the data, and drafted the manuscript. S.D. Johanningsmeier collaborated in the experimental design, supervised the research, assisted in interpretation of data, and reviewed and revised the manuscript. J.A. Osborne generated the statistical model for threshold data and provided general statistical consultation for other parts of the study.
